THE TREATMENT OF URICACIDEMIA.[1]

BY JOHN L. HEFFRON, M.D.,

OF SYRACUSE, N. Y.;

PROFESSOR OF CLINICAL MEDICINE IN THE COLLEGE OF MEDICINE OF SYRACUSE UNIVERSITY.

URICACIDEMIA is a condition the manifestations of which are so multiform that the consideration of the treatment of all its protean aspects is obviously beyond the limits of a short paper. It has already been demonstrated that every one of the acute or mature manifestations of this diathesis is but the expression in an individual of his peculiar reaction to the circulating acid excess or of the vulnerability of some one of his tissues or organs. This vulnerability of organ or tissue may be an inheritance. Whether a man develops arteriosclerosis from this irritant depends on the stuff his arteries are made of, not on chance. Heredity would determine whether the nerves had to bear the brunt of the burden, or the liver, or the kidneys, or the joints, or the muscles. But in all cases there is the underlying common condition, which must be overcome, else there is no such thing as a permanent cure. In this discussion, therefore, the problem which I set myself is the proper management of the daily lives of that large class of individuals who present any of the ills arising from imperfect metabolism and deficient excretion of nitrogenous waste.

It must first be pointed out that the individuals making up this class do not belong to a group that can be characterized by common points of resemblance. They may be plethoric, fat, and hearty; they may be anemic, thin, and sour, like the "lean and hungry Cassius," or they may be athletic in figure, strong in body and mind, passionate, and high livers. It is because of this diversity that the treatment of this condition cannot be reduced to rules that are hard and fast, a sort of "cut-and-dried" treatment that once learned is always available. It must be because of this diversity and the tendency in writing to confine one's thoughts to a particular class of cases that we observe such apparent contradictions in the recommendations of the leading authors upon this subject. The underlying condition is an increase of the uric-acid ratio to urates, so that free uric acid is present in excess in the blood or is deposited in the tissues. It is caused by a too abundant supply of uric acid in the food taken, or by an excessive formation of uric acid within the body, or by a changed condition of the blood, making impossible the solution of the normal amount of uric acid, and so interfering with its proper excretion. The indications then are to eliminate the excess, and to prevent its formation. As the excess is caused, first, by the too free consumption of foods containing uric acid; secondly, of foodstuffs from which it is made; and, thirdly, of such articles of consumption as by their nature give rise to imperfect digestion and to fermentation and acidity, thus diminishing the normal alkalescence of the blood, and interfering with the perfect elimination through natural channels of the nitrogenous waste material, the regulation of the diet is, therefore, clearly proven to be of the utmost importance. This is agreed to by all. However, if one should take a list of articles commonly used for the diet of man, and strike from it the foods interdicted by eight or a dozen accredited authorities, one would have in the end hardly water enough to keep the blood fluid, and almost nothing to eat. I do not propose to analyze the dietaries of various authorities, but give those which in my experience have proved of most value, easiest inculcated, and easiest adhered to.

There are a few general directions given to all, fat or lean, weak or strong, plethoric or anemic. I exclude from the dietary of all lithemics, all soup stocks, broths, and meat extracts, because they contain all the waste in the animal tissues from which they are made, and little else, and can but add embarrassment to eliminating organs already overburdened. I exclude sweetbreads, kidneys, liver, and *pâté de foie gras*, because they contain excessive amounts of urates, and greatly increase the output of uric acid. I exclude all acids and acid fruits, and include in this exclusion all beers and wines because of their acidity, for the reason that acid ingesta, even though they may combine with alkalies to form salts, do so at the expense of a complete chemical metabolism of nitrogenous waste, and, furthermore, because in the lithemic, they often disagree and disturb digestion. If the uricacidemia is pronounced, I exclude tea, coffee, chocolate, and cocoa, because of the close chemical resemblance of caffein and theobromin to uric acid, and because, clinically, I have found patients with marked symptoms do better without them. Another direction

[1] Read before the Syracuse Academy of Medicine.

that is applicable to all, save in the beginning of the treatment of the plethoric obese, is to use pure drinking-water in quantities larger than ordinarily consumed, but within the average physiological limit of five pints in every twenty-four hours. The water is to be drunk hot, a half hour before each meal and at bedtime, sipping it leisurely, if constipation be the natural habit; or cool, though never iced, commencing an hour and a half after eating, and continuing its use at intervals up to within a half-hour of the next meal, if the bowels are naturally inclined to free daily movements. These are the only general laws that I have found of undoubted benefit in the diet of all lithemic patients, and I dare say that with these my experience may not coincide with that of others of equal opportunities for careful observation.

The next question of importance is, To what extent can nitrogenous foods, meat, fish, eggs, milk, cheese, and the legumins be allowed, and what selections shall be made and why? A certain proportion of nitrogenous food is an absolute necessity for perfect nutrition. This class of foods is the only class that, with water, is sufficient for the perfect nutrition of man. Nansen, in his "Farthest North," describes most graphically his long Arctic winter in a cramped camp after he had left the "Fram." The sole article of food was bear's meat, and he asserts that after many months of this diet they experienced absolutely no inconvenience from its use, and had little repugnance for it and little longing for other food. Those who saw him and admired his physique could have little question but that he had been perfectly nourished. It would be interesting to know in detail the effect upon his organs, particularly upon his heart, his arteries, and his kidneys of this prolonged use of a purely meat diet. The flesh of animals is the chief source of nitrogenous foods. It is more easy of digestion than are the legumins or grains that contain nitrogen, and for many, more easy of complete elaboration than are milk and cheese. It has one great disadvantage in the treatment of the lithemic; it contains in the intercellular lymph-spaces the nitrogenous waste of the animal from which it has been derived. In using it, therefore, one is sure to get not only the albuminoids of the tissues, but preformed chemical bodies representing the waste of the tissues in the animal itself. This disadvantage is often overbalanced by the easier digestion of the tissues, so that, in certain cases, particularly in the dyspeptic anemics and in those having an idiosyncrasy for milk, a free use of animal food is followed by better results than attend the attempt to go without it. With those presenting a normal blood-count and a normal percentage of hemoglobin, with marked uric-acidemia, and without iodiosyncrasy against milk, it is best to exclude all butcher's meat, fish, and game. In such, milk, cheese, and eggs, which contain no uric acid or other waste products, and mushrooms, the grains and legumins, so prepared as to be easy of digestion, should entirely take the place of meats, until all uric-acid excess has been removed. Then, and in cases where the symptoms are less marked, a moderate amount of fish and meat may be allowed, say once daily.

The selection of the particular variety of meat and fish has always been considered a matter of considerable importance. There has been prevalent, and still holds, a notion that the white meats are less injurious than the red, that fish is allowable when meats are to be excluded, and that the flesh of immature animals is more injurious than that of the fully developed species. I have endeavored to ascertain the basis of this opinion. It is certainly not based upon scientific analysis of the foods mentioned, and must be, therefore, the results of clinical observation. It cannot be satisfactorily demonstrated that white meat contains less uric acid than red meat, or that the meat of young animals is more heavily charged with the products of nitrogenous waste than that of the mature species of the same kind. It comes then to the question of digestibility, and that depends as much upon the condition of the flesh of the particular animal under consideration, as upon its species or age. The fiber of the breast of the chicken, the partridge, and of hares is short and easy of disintegration, if in perfect condition. In England the Southdown mutton, grown only for its flesh, is the perfection of its kind. We cannot say the same of mutton in America. In Germany beef is not the favorite dish, and is never served except boiled. In our country, Western beef is probably the most perfect specimen of flesh food that can be found in the world, unless one excepts the English mutton. Ham, so largely prescribed by our German *confrères*, either raw or boiled and sliced cold, is seldom recommended by American or English physicians, though worthy of our consideration. Veal, spring lamb, and spring chickens contain a much larger proportion of water, and to many stomachs are difficult of digestion, and to some distinctly cathartic, while to others they are acceptable. Among fishes it is probably true that the color of the flesh has little to do with its acceptability as an article of diet. But, on the other hand, it is undoubtedly a fact that the fishes with white meat are generally easier of digestion than those which are darker, not because of their color, but because the fibers are more easily disintegrated and

so more digested. It would thus seem that the selection of the particular variety of meat or fish to be allowed should be left largely to the taste and experience of the patient. However this may be, it is sure that there can be no question as to the exclusion of the process of cooking flesh in fat, and of all made dishes of meats previously cooked, except plain hash, because of the enormous increase in the work of the organs of digestion inevitably involved.

In those cases where it seems necessary to exclude all meats, the nitrogenous element of food is best supplied by milk and eggs. Commercial milk is an unnatural product. By centuries of training man has produced an animal that, with enforced limitation of exercise, with forced feeding, and with artificial imitation of the process of suckling, is now capable of producing a lactiferous fluid the whole year round. The conditions of her unnatural existence are the cause of the diseases that, mostly from a commercial standpoint, are attracting the attention of the State boards of health everywhere. Pure milk, from a healthy cow, is ideal food for a calf, and, because man is a mammal, and other mammals are not so tractable, the milk of the cow is the selected representative of this class of foods. Milk from healthy cows is alone sufficient for the nourishment of man. It is food and drink. But I need not dilate upon this subject, for the experience of all here will illustrate the fact that the lithemic patient has, in numerous instances, not only lived, but thrived and worked and gotten rid of his diseases on a purely milk diet. Some cannot take it. It is unfortunate for them, but, being one of the unfortunates, I find there are compensations. Right here I may be permitted to say that physicians sometimes err in not studying the personal dietetic idiosyncrasies of those who seek their advice. A gentleman once said to me, "I have received such different advice from reputable doctors on the matter of diet, that I have just about concluded that doctors cut out things they can't eat themselves, and advise what their own palates approve." Is it not well to remember that there is an underlying truth in that very old saying, "What is one man's meat is another man's poison"?

It has often seemed that sufficient heed is not paid by the medical adviser to the emphatic protests of a patient against certain articles of diet with which he has had repeated unfavorable experiences. Eggs, raw or lightly boiled, furnish nitrogenous food, generally easy of digestion and of assimilation. To a few persons, eggs are distinctly poisonous. When cooked, the yolk is easier of digestion than the white. It is difficult to get an egg properly cooked. Egg albumen coagulates at 150° F. It is easiest digested raw. When cooked for delicate stomachs, it should either be allowed to stand on the table in water that has boiled, and the temperature of which is just under the boiling-point, or it should be broken into a cup and cooked in a water bath, with constant stirring, until the white just begins to cloud. If cooked more, it should be boiled for a half hour. I have frequently seen an egg so cooked digested with greater ease than one so-called soft-boiled. In those few cases where the entire egg cannot be digested, the whites can always be taken raw in milk or water or fruit-juices, in large numbers daily, without influencing unfavorably the digestive process.

Whether sugar should be allowed or not depends on individual peculiarities. From the obese, whether plethoric or anemic, it should be entirely withdrawn, and its use supplanted by saccharin. In the thin, if it is digested as sugar, and does not cause fermentation, its use in fair amounts is permissible and to be encouraged. Confectionery is so seductive, and the best of it so impure, that any but the simplest forms of pure sugar candies should never be allowed. The malted grains and the malted foods serve an excellent purpose with those in whom starch digestion is imperfect and sugars cause fermentation. The dietary of the lithemic includes all the grains that are capable of easy digestion—and each stomach is a law to itself in this particular—all vegetables that are not acid and not provocative of indigestion, and all sweet and subacid fresh fruits, raw or cooked. The popularity of vegetables as food depends very largely on the cook. There are very few vegetables cooked by simply boiling in hot water, after the style of the English, that anyone would eat, except as a matter of duty. The French and the Germans, on the other hand, bestow infinite pains on the preparation and cooking of vegetables, and serve dishes that are a surprise and a delight to those who have had no experience with the possibilities of vegetables. The digestibility of vegetables commonly excluded from the dietary of all save the most robust in active out-of-door employment can also be compassed by skill in the cook. That this is not done the menu of any first-class establishment shows. There, the chéf pays his careful attention to the soups, the meats, and the *entreés*, and a first-class pastry cook attends to the desserts, while the vegetables are relegated to a second or third-rate helper. Our habits of eating copy closely those of the English. We are expert judges of meats, and are heavy meat eaters, with an extra "sweet tooth" of our own. We know just how to cook meats, but we have much to learn of the value of vegetables as food and of their possible attractions to the palate. With the exception of those vegetables that contain oxalic acid, *viz.*, to-

matoes, rhubarb, sorrel (which Americans seldom use), and asparagus, there are none which need be excluded from the diet of the lithemic, unless for reasons of personal inability to digest them easily, but, as indicated, this objection can, in a large measure, be overcome by skill in cooking.

The liberal use of fruits should be encouraged. In those in whom the diathesis is little pronounced, even acid fruits may be allowed in moderate quantities, while the sweet and subacid fruits should be freely used. If the constitutional manifestations are marked, such fruits as strawberries, sour cherries, currants, gooseberries, cranberries, lemons, limes, and grape fruit are better omitted, while in the preparation of subacid fruits Fothergill's suggestion of stewing with a little soda should be observed. The banana is a fruit of peculiar value when it can be obtained mature and ripe. It contains seven per cent. of nitrogenous matter, and, when ripe, the starch and sugars are in such condition as to be very easy of digestion. The banana is the only fruit from which a palatable flour can be made which can be used by those (even young children) of especially weak digestion. There remains a word to be said about nuts. They are are palatable, and just now fashionable. They are certainly of considerable value as food, and are easily digested by some persons. The salted almond is probably the best representative of this class, while the vulgar peanut, roasted, makes a very good second. Very few who eat nuts liberally class them as foods, and therein lies the mistake. They eat them as a pastime, as children in the country eat popcorn and apples. If individual experience proves that nuts are easily digested, and if they are taken as a recognized part of a meal, there is no scientific reason for forbidding their use. Their variety is great, but they differ chiefly in flavor and in the relative proportion of fats and starch. Each palate is its own best guide in their selection, but any variety chosen should be fresh and sweet. In the diet of children, especially of lithemic parents, the same care in the selection of food must be made as with their elders. I have seen the too free use of meat extracts and juices followed by symptoms as pronounced and distressing in children as in adults, and have recorded as signal successes from the regulation of their dietary as in any case yet observed.

Of even more importance than the quality of the food is the regulation of the amount taken. Most people overeat. Except in the anemic and feeble, the limitation of the total amount of food taken is necessary, and with them it must be regulated. In reforming a diet it is not wise to make radical changes suddenly. If the heavy feeder be put on light diet and little of it, from his standpoint, he will soon rebel and return to his groaning table. Even Haig recommended that advantage of the cooler months be taken in reforming the dietetic habits of many patients.

Next to diet, the question of exercise is the most important. If the person with the gouty diathesis could take sufficient exercise to get up a good perspiration, and so aid the elimination of the waste products through the skin every day in the year, it is probable that no acute manifestations of his diathesis would ever supervene. How to get our patients of this class to exercise has been a difficult problem to solve, but with the advent of the bicycle and its fascinations the problem has been greatly simplified. Exercise for health's sake is always stupid, but a spin on a wheel, or an athletic game, lawn tennis, golf, or baseball, or an outing with rod, gun, or camera, or a half-hour's fun with an elastic exerciser, has attractions that the physician should avail himself of in prescribing. When the enfeeblement is too great for active physical exercises, massage and Swedish movements must be resorted to, and are capable of doing the greatest amount of good. The lithemic should be taught that a daily bath is a necessity, and a weekly Turkish bath more than a luxury. A hot air, steam, or water bath, once or more a week, does more than cleanse the skin; it stimulates one of the greatest organs of elimination and actually rids the system of an enormous amount of nitrogenous waste, thus relieving the kidneys of a proportion of their work, already too burdensome. It stimulates the nervous centers, and facilitates the process of metabolism in the tissues. With attention to diet, exercise, and bathing, the lithemic may so regulate his life as to be free from all acute manifestations of his inherited or acquired condition. But it must become a habit, and must be continued as long as his environment and innate tendencies remain the same, else he will certainly relapse into his former condition, and pay the penalty in an enfeebled, painful, and crippled existence.

As an addition to the hygienic measures referred to, I am in the habit of recommending the habitual daily use of some alkali. If there is an absence of all symptoms, and if the urine shows a normal uric-acid ratio, it is necessary simply to drink a glass of water at bedtime, made slightly alkaline with citrate or bicarbonate of potash, five to ten grains, or of bicarbonate of soda. Lithia was formerly supposed to be more powerful as a solvent, but the claim has not been capable of demonstration, and Haig says it has no value in rendering the blood more alkalin. He claims to demonstrate that it does not unite with

uric acid, making the soluble urate of lithia, but with other acids, the salts of which would make the blood more alkaline. It is certainly less easily borne and more provocative of indigestion, in corresponding doses, than are those of the other alkalies. If the condition is marked, there is no remedy that has given me results comparable to salicylate of soda. Salicylates made from the natural acid are more palatable, and less disturbing to the digestion. Small doses, highly diluted, and repeated not more than twice or three times a day, are sufficient, unless true gouty symptoms arise. In such cases, if the salicylates are given until they evoke their physiological effects, as good results are obtained as by the use of colchicum or other remedies, and there remains the satisfaction that the remedy used has not been simply symptomatic, if we can accept as true the many recorded experiments on the influences of the salicylates on the excretion of uric acid, and on the blood. There are innumerable alkaline mineral waters that are exploited as specifics. They are no more specifics than is any solution of alkalies in water. Some of them are palatable, and by presenting a combination of several salts in an aerated water, offer some advantage to those by whom expense need not be considered. My personal preference is for Vichy, either the imported or the Saratoga Vichy. The habitual use of this or of the milder Apollinaris is to be commended to those who can afford it.

It would be interesting to discuss the value of many measures and remedies proposed for the alleviation of this condition, but to review the value of mineral springs and mineral baths, the effect of climate, and the relative merits of many proposed lines of treatment, would take too long, and yield too little. I end as I began, in the assertion that enforcement of a proper dietary, active exercise, and daily baths are of the chief importance.

THE AMERICAN PEDIATRIC SOCIETY'S COLLECTIVE INVESTIGATION ON INFANTILE SCURVY IN NORTH AMERICA.[1]

THE subject of infantile scurvy has so recently come into prominence, and still presents so many mooted questions, especially regarding its etiology, that it was the decision of the American Pediatric Society a year ago to undertake a collective investigation of the matter, based upon the cases occurring in America. This seemed particularly needed, as no other such study upon a large number of cases has yet been made in any country.

The committee, which is now making its report, was accordingly appointed. It has been diligently at work during nearly a year, and has used every means in its power to reach reports of cases of the disease. A list as accurate as possible was prepared of all the medical journals of North America, and a notice of the proposed investigation was sent to each, inviting correspondence on the part of all readers. Letters were sent to the secretaries of the county societies in a large number of the the States of the Union requesting that notice be given at the meetings. Letters were also addressed to the professors of diseases of children in all the regular medical colleges of the United States. The "Index Medicus" was searched for the names of those who had published reports of cases, and letters were addressed to all of them, as indeed to all physicians of whom even the rumor had come of probable cases under their charge. Circulars were printed containing questions to be answered, and were sent to all the members of the American Pediatric Society, to all physicians applying for them, and finally wherever there seemed any chance of getting a response.

The questions contained in the circular requested information on the following points: Whether the case was seen in hospital or private practice; the race, sex, and age; the hygienic surroundings, family history, and previous illnesses; full details of feeding from birth, and the influence which the food appeared to have had upon the development of the disease; the symptoms in detail, with special reference to pain and its location, apparent paralysis or inability to move, swellings, fractures, hemorrhages, the condition of the gums, the presence of fever, the condition of the urine and bowels, the presence of anemia or malnutrition and of rickets or any other complicating diseases, and the character of the first symptom to develop; the treatment in detail, with duration of illness, and the time before decided improvement was discovered; the direct cause of death in fatal cases, and the *post-mortem* findings; and finally, whether the case had been published previously.

The committee has been surprised and pleased at the large number of replies received. There are other cases of which it has knowledge of which no reports could be obtained, and undoubtedly, many more whose existence was not discovered. But in all the committee has collected 379 cases seen by 138 observers. Some of the cases are very incompletely reported, but in the majority of instances the answers are for the most part satisfactory. No cases needed to be excluded as instances of mistaken diagnosis, although a very few were somewhat doubtful.

The topics covered by the questions can best be taken up for the most part seriatim, stating merely what the reports state, without vouching for the correctness of opinions.

Race.—The race to which the subjects of the disease belong is stated in 372 cases. It is not given with definiteness sufficiently often to allow of an analysis further than to say that there were 367 white, 4 black, and 1 Chinese.

Sex.—Sex shows out of 372 cases, 189 male, *i. e.*, 51 per cent.; and 183 female, *i. e.*, 49 per cent.; a difference not decided enough to indicate that sex is an etiologic factor. In the remaining cases the sex is not mentioned.

[1] Reported at the Tenth Annual Meeting, Cincinnati, June 2, 1898.

Age.—Age is a very important matter. Although strictly speaking, the age of the cases of infantile scurvy should be limited to those under two years, the committee has ventured to include a few in children, slightly or decidedly older than this, since the etiology and symptoms are not different in any respect. Question IV. on the circular reads: "Age When Seen with Scurvy," while XIV. reads: "Duration of Illness before Treatment Was Commenced." By combining the answers to these two questions, the age at which the illness developed could be determined in most instances. Reliable information was given in 359 cases; in the remaining number the age was unknown or was not stated. The accompanying tabular arrangement shows the number of cases developing at different ages:

AGE WHEN SCURVY DEVELOPED.

Age.	No. of Cases.	Per-centage.	Age.	No. of Cases.	Per-centage.
3 weeks,	1	.27	16 months,	7	1.70
1½ months,	1	.27	17 "	6	1.67
2 "	3	.83	18 "	7	1.70
3 "	2	.55	19 "	4	1.11
4 "	9	2.50	20 "	2	.55
5 "	5	1.40	22 "	1	.27
6 "	13	3.62	23 "	1	.27
7 "	33	9.19	2 years,	2	.55
8 "	41	11.42	2 years, 3 mos.	1	.27
9 "	47	13.09	2 " 6 "	1	.27
10 "	51	14.20	2 " 7 "	1	.27
11 "	26	7.24	2 " 8 "	1	.27
12 "	25	7.00	3 " 6 "	1	.27
13 "	25	7.00	4 " 2 "	1	.27
14 "	22	6.12	6 "	1	.27
15 "	17	4.73	9 "	1	.27

It will be seen that the disease is most apt to develop between the ages of seven months and fourteen months, inclusive. The youngest case was that reported by Dr. A. Matheson of Neillsville, Wis. This was a child of four weeks who had already been ill five days when first seen. The child was fed at the breast. Its hygienic surroundings were poor. The disease exhibited perfectly typical symptoms and ended fatally.

The oldest child, reported by Dr. J. H. Fruitnight, was one of nine years, and was also a typical case, rapidly recovering under dietetic treatment. The cause appeared to be improper diet.

Social Position.—Of 379 cases it is interesting to note that 83 per cent. occurred in private practice, and only 17 per cent. in hospital practice. Although no absolute class distinctions can be based on these figures, yet they point very positively to the greater tendency of the disease to occur among the rich or the well-to-do. This tendency is still further illustrated by the statements of the writers regarding the *hygienic surroundings* of the cases. In 303 cases these are described as good, and often the statement is volunteered that they were of the very best. In 5 they were doubtful, and in only 40 are they described as bad. The figures of the report would therefore seem to indicate that the influence of bad hygienic conditions upon the etiology of the disease is extremely limited.

Previous Health.—Out of 285 cases suitable for study, it is distinctly stated in 167 that the previous health had been good. In 118 the child had suffered from various diseased conditions which may be enumerated as follows:

Bronchitis, 5; chickenpox, 1; constipation, 1; convulsions, 3; cretinism, 1; diarrheal conditions, 45; eczema, 1; furunculosis, 1; indigestion, 22; influenza, 6; malaria, 1; measles, 7; pneumonia, 5; rheumatism, 1; scurvy (previous attack), 1; scrofulous diathesis, 1; typhoid fever, 1; whooping-cough, 2.

It is evident that the occurrence of most of these diseases can only be considered as accidental. There is a striking preponderance of instances of digestive disturbance. This probably is an indication that the faulty diet which occasioned the scurvy produced the indigestion also. It is no proof that the digestive disease itself bore any etiological relation to the constitutional affection. This is clearly the view of the correspondents, for, in answer to the question of the circular, a belief in any other cause than diet is expressed in only twenty-four instances.

Rickets, anemia, and malnutrition are not mentioned in the foregoing list. They will be referred to later.

Attention may be called to the instance of a second attack of scurvy reported by Dr. L. E. Holt. The child was eighteen months of age at the time of the second attack, the previous one having developed four months before. The first attack followed the use of Mellin's food and sterilized milk. Recovery followed in a week upon a diet of sterilized milk and beef juice, no fruit juice being given. The second attack followed the use of Reed and Carnrick's soluble food. The patient in this attack was in a wretched condition and died in eight days.

The case of scurvy developing in a cretin, reported by Dr. A. Caillé is also interesting. The child was a typical cretin of fourteen months. Scurvy followed the use of condensed milk. Recovery was very prompt under the administration of sterilized milk, fruit juice, and cereals.

Family History.—This, too, appears to exert little or no influence. In 129 cases the family history is stated to have been good, and in 97 it is negative. In 74 the following diseases are mentioned in the family: Alcoholism, 2; anemia, 2; asthma, 1; carcinoma, 1; caries of the spine, 1; diarrhea, 1; eczema, 1; gout, 2; neurotic tendency, 6; paresis, 1; pneumonia, 1; rheumatism, 16; sciatica, 1; scurvy, 1; syphilis, 7; tuberculosis, 27; uricacidemia, 1.

Diet.—The most important etiologic factor, according to general opinion, is a dietetic one. Consequently, the committee has paid particular attention to this point. When correspondents did not make the matter quite clear in their answers, personal letters were addressed to them, asking for further information. A large number of such letters have been written, and replies received in most instances. Full details were asked regarding diet from birth onward, and the question of food used at the time the scurvy developed, or so shortly before that it might seem to be associated with it, was particularly emphasized. The question was also asked, whether in the opinion of each correspondent there was reason to believe that the disease depended on the nature of the food used. An affirmative answer was received in 275 cases; negative, and the disease attributed to other causes, in 24. The

committee is not in a position to judge of the correctness of this view, nor can it claim that the disease *did* arise in any instance as the result of the diet employed. It would merely make the following statements of the food employed at or shortly before the symptoms of scurvy were observed according to the reporters' replies.

Any accurate percentage analysis of the report is impossible, both because the correspondents have not always stated the exact nature of the food, and because in very many instances more than one form of food was given. Perhaps the following summary of some of the main divisions may be of value, remembering, however, that cases are repeatedly counted twice; *e.g.*, one case may be counted in the condensed-milk class and again in the sterilized-milk division.

Food Used at or Shortly before Scurvy Developed.—The number of cases in which the character of the food is specified, is 356, as follows:

Breast-milk.—Alone, 10; with raw milk and amylaceæ, 1; with sterilized milk and amylaceæ, 1; total, 12.

Raw Milk.—Alone, 4; with breast-milk and amylaceæ, 1; total, 5.

Milk (nothing said about heating).—Alone, 8; peptonized, 4; with amylaceæ, 4; total, 16.

Sterilized Milk.—Alone, 68; with proprietary foods, 21; with amylaceæ, 8; peptonized, 10; total, 107.

Pasteurized Milk.—Alone, 16; with proprietary foods, 2; with amylaceæ, 1; peptonized, 1; total, 20.

Peptonized Milk.—Nothing further stated, 3; sterilized, 8; Pasteurized, 1; with proprietary foods, 1; with amylaceæ, 1; total, 14.

Amylaceous Food (not proprietary).—Alone, 6; with breast-milk, 3; with milk, 5; with sterilized milk, 8; with Pasteurized milk, 1; with peptonized milk, 1; total, 24. (Nine of these were oat-meal).

Table Food.—Nothing else mentioned, 11; with condensed milk, 1; total, 12.

Mellin's Food.—Nothing further stated, 42; with condensed milk, 22; with sterilized milk, 16; with Pasteurized milk, 2; with other proprietary food, 1; total, 83.

Malted Milk.—Nothing further stated, 44; with cream, 1; with amylaceæ, 1; with other proprietary foods, 2; total, 48.

Condensed Milk.—Alone, 32; with milk, 1; with cream, 1; with other proprietary foods, 3; with table food, 1; total, 38.

Reed and Carnrick's Soluble Food.—13.

Imperial Granum.—6.

Liebig's Food.—Alone, 1; with condensed milk, 1; total, 2.

Lactated Food.—Alone, 3; with condensed milk, 1; total, 4.

Nestle's Food.—Alone, 1, with sterilized peptonized milk, 1; total, 2.

Among other articles of diet mentioned by correspondents, each in one instance, are: Gardner's food, Robinson's barley, Ridge's food, Brush's food, animal broths, Bartlett's pepsinated food, Lacto præparata with Malted Milk.

There are a number of instances in which the writers mention "proprietary foods" without further designation. In all 214 cases (60 per cent.) were fed on proprietary foods.

The effect of dietetic treatment has such an important bearing upon the etiologic influence of diet that the whole matter will be discussed more fully under Treatment.

Symptoms.—The symptoms in infantile scurvy are so typical and well known that they would appear to need little further study. Nevertheless, the attention which has been directed to them by the questions of the circular has not been without fruit.

First Symptom to Develop and Order and Time of Other Symptoms.—In response to this question the answers have not been altogether satisfactory. Undoubtedly in a large number such early symptoms as anemia and malnutrition were overlooked or were not included by the readers as symptoms of the disease. Then in a large number, perhaps the majority of cases, answers have not made it quite clear whether the correspondent intended that a certain number of symptoms developed in the order in which the names are written, or whether they all were noticed at one time. Presuming that the first is the writer's intention, we make the following statement of first symptom seen, basing this on 327 cases. The order of symptoms is too complicated and too uncertain to warrant a statistical arrangement.

First Symptoms Seen.—Pain and tenderness, 145; affection of gums, 42; interference with motion, 36; anemia, 27; cutaneous hemorrhages, 22; swellings, 16; restlessness, 6; anorexia, 5; debility, 5; diarrhea, 5; constipation, 2; hemorrhage from nose, 1; hemorrhage from mouth, 1; hemorrhage from rectum, 1; hematuria, 3; "hematoma of tongue," 1; irritability, 3; vomiting, 1; fever, 1; opisthotonos, 1; sweating, 1.

Pain on Motion or Handling.—Pain is clearly a very prominent symptom of the disease. Generally it is evident only when the child is moved, or tries to move itself. Sometimes it is so intense that the approach of any one to the bedside is sufficient to cause the child to scream out through fear of being touched. Pain is reported present in 314 instances. In most of the remaining, no answer was made, and it is probable that the symptom could not have been a prominent one. The locality of the pain in the cases where there were accurate details was as follows: Legs, 120; legs and arms, 25; legs and one arm, 11; legs and body, 4; one leg, 13; one leg and one arm, 1; one arm, 1; back, 1; back and legs, 1; back and leg, 1; back and thighs, 1; thighs, 1; hips and thigh, 1; one thigh, 2; one hip, 2; knees, 1; knees and ankles, 2; knees, ankles and shoulders, 1; knees, ankles and wrists, 2; knees and arms, 1; one knee, 1; one ankle, 1; ankles, 1; ankles and feet, 1; ankles and elbows, 1; elbow, 1.

Pain When at Rest.—In 91 cases pain seems to have been present, even when the child was still; while in 134 it is definitely stated as absent under this condition.

Interference with Motion.—The symptom variously described as *paralysis*, *pseudoparalysis* and *disability* or *unwillingness to move* is reported frequently. It probably depends in every instance upon pain, since there

is no evidence that actual paralysis occurs in the disease. In 319 cases interference with motion of this nature existed. Rigidity is described as present in 96 cases and absent in 106. It is due to pain in most instances, but perhaps in others may have been occasioned or increased by the presence of swelling. The parts of the body in which motion has been interfered with in any way in the cases reported, and the locality mentioned in detail, may be enumerated as follows: Legs, 159; legs and arms, 55; legs and one arm, 14; legs and one hand, 2; one arm, 3; legs and thighs, 1; thighs, 3; one leg and one arm, 1; one leg, 27; one thigh, 2; hips, 1; one hip, 2; one hip and thigh, 1; one hip and knee, 3; hip, leg and shoulder, 1; hip, elbow and shoulder, 1; one knee, 4; one ankle, 2; ankles, knees, hand and wrist, 1.

Position of the Limbs.—To a question regarding the position of the limbs, about which Barlowe speaks so definitely, there have been replies in 205 cases. In 17 of these the position was normal. In the balance we find the position of the limbs as follows: Flexed, 152; extended, 23; flexed and abducted, 1; flexed and adducted, 1; flexed and everted, 1; abducted, 1; everted, 3; everted and extended 2; toes extended, 1; feet extended, 3.

Weakness of the Back.—The occurrence of weakness of the back, a symptom which Barlowe says is marked, is mentioned as present in 97 of the cases reported to the committee, and as absent in 108. In the remaining nothing is said of it.

Depression of the Sternum.—This condition is likewise emphasized by Barlowe as being sometimes striking and characteristic. It is mentioned in 34 cases, but said to be absent in 170 others. It is not certain in the cases of the report how frequently the condition had developed acutely as a result of scurvy, and how often it had already been produced by a previously existing rachitis.

Swellings.—The effort has been made by analyzing the cases collected to determine the position of local swellings, whether these were situated in the joints or the shafts of the limbs, in the soft tissues or in the bones, and whether any redness was present. The answers are not clear in every instance, and are frequently somewhat contradictory, partly, perhaps, from failure of the observer to understand the question, and partly from lack of careful discrimination between subperiosteal and other effusions, and between effusion into a joint and that about it. The great irregularity also of the distribution of the swelling renders an accurate tabular arrangement too complicated. Remembering that in many cases more than one part of the body was involved, and that the figures given do not mean that only the portion mentioned is affected in these cases, the following division may be made: Joints (or probably oftener about joints) involved in 165 cases. Location given in 101; *viz.:* Knees, 73; ankles, 28; wrists, 12; hand, 1; elbow, 3; shoulder, 5; hip, 6.

Shafts of limbs involved in 197 cases. Location given 123; *viz.:* Thighs, 59; legs (below knee), 16; "legs" (not further stated), 11; forearm, 5; upper arm, 4; "arm," 5; ribs, 1; scapula, 1; ilium, 1.

The gross results of the answers regarding the tissues in which the swelling occurred gave: Swelling in soft tissues, 97: swelling, subperiosteal, 114; swelling in both situations, 16. In 69 cases the swollen parts were reddened also. It is stated that there was no redness in 121. A more general swelling, to be classified rather as edema, is described in 68 cases and stated to be absent in 98. In regard to the swelling or protrusion of one or both eyes which has been described by writers, the symptom is said to have been absent in 110 cases and is reported present in 49. In 9 of these swelling only is mentioned, in 18 protrusion only, and in 22 both are referred to.

Gums.—The condition of the gums and mouth is one of extreme interest. In 16 cases it is distinctly stated that the gums were entirely unaffected, while in 313 they were diseased. The degree of involvement varies from slight swelling to great sponginess and even ulceration. The degree and form of the affection in the cases suitable for study may be seen in the following table: Swelling, absent, 14; present, 293; sponginess, absent, 27; present, 249; discoloration, absent, 23; present, 259; bleeding, absent, 64; present, 188; ulceration, absent, 101; present, 91, The relation of the affection of the gums to the presence of teeth is of much interest. In nearly all the cases of scurvy in this report teeth were present, but what influence this has is not quite clear, since experience teaches that, curiously, it is usually the gums of the upper jaw which are most affected, although the lower teeth naturally are the first cut. Statistics on the portion of the gums involved were not furnished sufficiently to allow of conclusions; but regarding the teeth it is to be noted that of 359 cases suitable for comparison, teeth had already appeared in 314 instances, *i.e.*, 87.5 per cent.; while in only 45 cases, *i.e.*, 12.5 per cent., were there no teeth. In studying more carefully these 45 cases of scurvy without teeth, we may make the following analysis: No teeth, gums normal, 21 cases; no teeth, gums affected, 24 cases. The conditions present in the latter group were as follows: Swelling, 19 cases; sponginess, 14 cases; bleeding, 5 cases; discoloration, 17 cases; ulceration, 4 cases. This is a proof that affection of the gums may occur equally well when there are no teeth as when teeth have developed. The fact that in the great majority of cases of infantile scurvy the presence of teeth and the affection of the gums is associated, depends merely on the fact that the disease generally develops at an age when teeth naturally have been cut.

Cutaneous Hemorrhages.—These have occurred with frequency in the cases reported. Accurate data are given in 353 cases. Of these, cutaneous hemorrhage is reported present in 182 and absent in 171. There is much doubt about the accuracy of the writers in their classification of the hemorrhages according to size, and to the proper use by them of the descriptive names employed, inasmuch as the question on this point did not specify clearly. In 99 instances the presence of "ecchymoses" is mentioned. In 83 "purpuric eruption" is reported, and in 37 "petechiæ." In 13 the nature of the lesion is not specified.

Hemorrhages from Mucous Membranes — Data are available in 361 cases. Of these were no hemorrhages

from any mucous membrane in 196, while in 164 they occurred. In 93 cases there was hemorrhage from the mouth. This includes the cases where bleeding from the gums is described by writers. In 33 cases there was bleeding from the nose, in 2 from the stomach, and in 37 from the bowels. Cases of hematuria are not included here, and will be referred to later.

Fractures.—Fractures in infantile scurvy are usually separations of the epiphyses merely. Even this would seem to be rare, for fractures of any kind is mentioned in only 9 of our cases. In 342 it is distinctly stated to have been absent, and in the remaining the question is not answered.

Fever.—Probably in the majority of the cases of the disease upon which this report is based no temperature record has been made. In 93 cases it is stated that there was no fever; in 182 it was present and in the remaining no answer is given. In the cases where present it is described as slight in 116 instances, moderate in 23, high in 8, and irregular in 6. Clearly, fever is not a prominent symptom of the disease, and probably often, when present, depends on accidental causes.

Bowel Movements.—The following conditions are mentioned: Bowels regular, 74; bowels irregular, 15; constipation, 126; diarrhea, 65; bloody diarrhea, 12.

Urine.—Judging from the number of instances in which no answers have been returned, no examination of the urine has been made in most of the cases. It is reported as examined for albumin in 163 cases: in 33 of these albuminuria is reported and in 130 it was absent. Tube casts were present in 13 instances, absent in 13, and no observation reported in the others. Properly speaking the occurrence of hematuria should be discussed under the title of hemorrhage. It is mentioned as present in 22 cases only. Of other abnormal conditions of the urine the following may be mentioned: Urine very acid, 1; urine scanty, 9; urine suppressed, 1; urine increased in quantity, 3; glycosuria, 1; hemoglobinuria, 1; pus (from cystitis), 1; phosphates increased, 1; chlorids increased, 1.

Anemia; Malnutrition. — These conditions, already referred to as often the earliest symptoms of infantile scurvy, may have been the first evidences of the disease in many of the cases on which this report is based. In other cases they must be regarded as complicating affections only. Answers are not full enough to allow of satisfactory conclusions on this point.

Anemia is said to have been present in 254 cases, as follows: Anemia present (without specifying degree), 47; anemia slight, 66; anemia moderate, 32; anemia marked, 109.

Blood examinations were made in 15 cases and the conditions noted as follows: The percentage of hemoglobin was much reduced in all the cases, 8 in number, in which an examination was made, some being as low as 35 per cent. Of the 7 cases in which the red blood-corpuscles were counted, all showed a reduction except 2. In these 2 the number was normal or nearly so, but the hemoglobin was 50 and 35 per cent., respectively. Leucocytosis was present in 5 cases, poikilocytosis in 2. In only one instance was there a differential count of the leucocytes made. Of 217 cases in which the question is answered, emaciation is recorded in 167 and is said to have been absent in 50. Malnutrition was observed in 178 cases out of 216, in which replies were made as follows: Malnutrition present (without specifying degree), 108; slight, 20; moderate, 7; marked, 43.

Rickets.—Infantile scurvy has so often been described as "scurvy rickets" and "acute rickets," that the investigation of the actual relationship of the two diseases was one of the matters to which the committee directed especial attention. The question upon the circular reads as follows: "(*a*) Any symptoms of rickets present? (*b*) Slight or well marked? (*c*) What relation in time of development did they bear to the scurvy?" Satisfactory answers were received in 340 cases; in 152 of these (45 per cent.), there were symptoms of rickets present, slight in 72, marked in 64, and the degree not mentioned in 16. In the remaining cases (55 per cent.), rickets is definitely stated to have been absent. With regard to the relation in time of development, it is stated in 50 cases that the rickets was first present; in 14 that it developed with the scurvy, and in 2 after it. There does not seem to be evidence as far as this investigation teaches that the association of rickets and scurvy is at all intimate. Very possibly the same defect in diet which produced the one produced the other also, but the rapid recovery under treatment which the scurvy underwent did not apply to the rickets. This seems to indicate only accidental association of the two diseases; certainly not any causal relation between them.

Other Complicating Conditions.—A variety of affections are mentioned complicating scurvy in a number of cases, as follows: Bronchitis, 5; cretinism, 1; enlargement of inguinal glands, 1; "cerebral symptoms," 1; convulsions, 1; pneumonia, 2; boils, 1; irritability, 1; vomiting, 4; eczema, 2; enuresis, 1; sweating of the head, 1; tympanites, 1; caput medusæ, 1; diaphoresis, 1; pertussis, 2; insomnia, 1; anorexia, 2; post-nasal discharge, 1; measles, 1; restlessness, 1; phimosis, 1; indigestion, 2; laryngismus stridulus, 1; cystitis, 1.

Diagnosis.—The study of diagnosis has been only incidental, based upon the mistakes made before the disease was recognized in certain cases. The only disease for which infantile scurvy was repeatedly taken appears to have been rheumatism. In several instances the affection of the legs was supposed to be due to sarcoma. The apparent paralytic condition has also been the cause of error in some instances.

Duration of Illness and Prognosis.—The disease is essentially chronic, its course terminating only on the institution of proper treatment. This seems to be proved by the answers contained in the circulars. To the question concerning the *duration of the disease before the case came under observation*, replies were received in 306 cases.

Intensely interesting in this connection are also the replies to the next two questions: First. *Duration of illness after treatment was commenced*, and second, *duration of treatment before marked improvement was noticed.* To the first question replies concerning 308 cases were

received. Of course those fatal during the attack of scurvy are not included here nor those which passed from observation.

DURATION OF THE DISEASE BEFORE TREATMENT WAS COMMENCED.

Days.	Cases.	Weeks.	Cases.	Months.	Cases.
2	3	1	15	1	18
3	3	2	33	2	42
5	2	3	58	3	31
8	1	4	22	4	14
9	1	5	8	5	4
10	9	6	29	6	7
24	1	7	6	7	2
		8	1	10	1
		10	3	12	1
				2½ yrs.	1

Still more striking are the answers to the second question, as to the time when marked improvement was first noticed. There are 311 cases suitable for study in this category, excluding fatal cases and those passing from observation as before. The replies are often astonishing. Nothing is more striking than the speed with which these reports show a grave constitutional disease disappearing under proper treatment. There is certainly no disease for which a more specific treatment can be said to exist. The replies to the last two questions may be conveniently stated in the following tables:

DURATION OF TREATMENT BEFORE MARKED IMPROVEMENT WAS NOTICED.

Days.	Cases.	Weeks.	Cases.	Months.	Cases.
1	19	1	47	1	6
2	58	2	27	2	4
3	46	3	8	3	4
4	26	4	1		
5	19	5	1		
6	1	6	1		
7	2				
8	2				
9	1

Treatment.—Not so much could be learned of the value of treatment as could be desired on account of the fact that in nearly all cases we have a combination of diet and of medicinal measures, including the use of fruit juices, and it is impossible to determine absolutely which was the active curative agent.

Taking the cases in which treatment was effectual and which are suitable for study, the results may be stated as follows:

I. Cases recovering under treatment with drugs only (no change in diet) 0
II. Cases recovering under the use of fruit juice alone (no change in diet) 3
III. Cases recovering under the use of beef juice alone (no other change in diet) 2
IV. Cases recovering under the use of beef juice and fruit juice combined, with or without drugs (no change in diet) 6
V. Cases recovering under the combined effect of change of diet, often including beef juice, and employment of fruit juice, with or without drugs 257
VI. Cases recovering under change of diet, often including beef juice, and use of drugs (no fruit juice) 20
VII. Cases recovering under change of diet alone, often including beef juice (no fruit juice) 38

These last two may be properly considered together, since there is no evidence that any treatment with drugs has an appreciable effect upon the disease. So many of the reported cases were treated with drugs alone without result before the correct diagnosis was made and other treatment instituted, that this belief is amply justified. Combining, therefore, divisions VI. and VII., and comparing the statements of the writers regarding the diet employed during treatment and that employed when the scurvy developed, we may make the following table based upon fifty-eight cases.

Again the committee would state that no claim is made that the recovery was the result of the change, but that it quotes merely the statements of the correspondents to the effect that recovery took place after the change was made.

VI. and VII.—Recovery Following Change in Diet Alone, with or without Drugs. (No Fruit Juice Employed.)

Mellin's food to milk and beef juice 2
" " to raw milk and beef juice 1
" " to modified milk 4
" " to modified milk and beef juice 2
" " to diet and beef juice 1
" " and sterilized milk to beef juice and broths 1
" " and sterilized milk to sterilized milk and beef juice 2
" " and condensed milk to modified milk, 1
" " and condensed milk to raw milk 2
" " and sarcopeptone to fresh milk and beef juice 1
Condensed milk to fresh milk and beef juice 1
" " to sterilized milk and diet 1
" " to lactated food and raw milk 1

Imperial granum to raw milk and beef juice	1
Patented food to diet	1
Ridge's food to diet	1
Diet (poor) to diet (better)	2
Bartlett's pepsinated food to fresh milk	1

It must be noted with regard to this table and those following that the term "modified" milk is used very loosely by the reporters. Occasionally it is specified to be laboratory milk, but much oftener this is not the case, and we are unable to know whether the modification was done at home or not, and whether the milk was heated or not. Presumably it was Pasteurized in many instances. Where the term "fresh" milk is employed in the table, we have been unable to learn by additional correspondence whether "raw" milk is meant or whether only a change from proprietary food to cow's milk is intended. The term "diet" as employed in the tables either expresses the fact that a large and varied number of different forms of diet were tried, too complicated to be detailed, or else quotes merely the statement of the writers that a change of diet was made, the original food probably being abandoned entirely unless otherwise stated.

The following table shows the food employed in divisions I., II., III. and IV., in which the diet was the same (except sometimes for the addition of beef juice), while the scurvy was developing and while it was recovering.

Recovery Following with No Change of Diet During Treatment.

I.	Treatment with drugs only		0
II.	Treatment with fruit juice only		3
	Mellin's food (milk sterilized)	1	
	Sterilized milk	2	
III.	Treatment with beef juice only		2
	Sterilized milk	1	
	Raw milk	1	
IV.	Treatment with combined beef juice and fruit juice only		6
	Sterilized milk	2	
	Sterilized milk and broths	2	
	" " " amylaceæ	1	
	Table food	1	

Division V. contains by far the largest number of cases, 257 in all. The changes in diet employed are much too complicated to be stated fully in the table. Moreover, they are of little value, since the treatment was such a composite one, *viz:* change of diet combined with the use of fruit juice in every case, and often of beef juice and of drugs as well. A few of the more striking classes of cases may be selcted as follows:

V.—Recovery Following Change of Diet Cimbined with Fruit Juice, with or without Drugs.

Condensed milk to milk, variously treated	23
Imperial granum to milk, variously treated	7
Lacto præparata to raw milk	2
Lactated food to milk	1
Reed & Carnrick's Soluble Food to milk, variously treated	3
Malted milk to milk, variously treated	38
Mellin's food to milk, variously treated	21
Mellin's food and condensed milk to milk, variously treated	19
Sterilized milk to fresh (probably always raw) milk.	34
Sterilized milk to Pasteurized milk	4
Pasteurized milk to "fresh" or "raw" milk	9
Pasteurized milk to sterilized milk	1
Raw milk to sterilized milk	1
Breast-miik to cow's milk, variously treated	6

The conclusions to be drawn from this combined study of etiology and of treatment seem justifiable only to the following extent: (1) That the development of the disease follows in each case the prolonged employment of some diet unsuitable to the individual child, and that often a change of diet which at first thought would seem to be unsuitable may be followed by prompt recovery. (2) That in spite of this fact regarding individual cases, the combined report of collected cases makes it probable that in these there were certain forms of diet which were particularly prone to be followed by the development of scurvy. First in point of numbers here are to be mentioned the various proprietary foods. (3) In fine, that in general the cases reported seem to indicate that the farther a food is removed in character from the natural food of a child the more likely its use is to be followed by the development of scurvy.

Fatal Cases.—Twenty-nine of the 379 patients are reported to have died. In 2 of these, death seems to have been remote from the attack of scurvy. Of the remaining 27 the causes as enumerated by the reporters are as follows: Exhaustion, 6; cerebral hemorrhage, 3; diarrhea, 2; bronchitis, 2; vomiting (?) 1; convulsions, 1; pneumonia, 4; malnutrition, 1; pulmonary hemorrhage, 1; ulcer of stomach, 1; syncope and nephritis, 1; doubtful, 4. It is difficult to determine in how many of these the scurvy itself could be held responsible for the death; probably in few, if any.

Autopsies.—There have been handed in to the committee the reports of six autopsies in all, some of them only partial. The salient points of each may be enumerated as follows:

Case of Dr. Caillé. Child of nine months; ill about three months. Autopsy showed hemorrhagic spots on the pericardium and surface of the liver; subperiosteal hemorrhage of the long bones. Case of Dr. L. E. Holt. Child of twelve months; ill for two months. Autopsy showed separation of the lower epiphysis from the shaft of the left femur; extensive subperiosteal hemorrhage of the left femur; subpleural hemorrhages; bronchopneumonia. Case of Dr. L. E. Holt. Child of thirteen months; ill about two months. Autopsy showed subperiosteal hemorrhage and separation of the lower epiphysis of the left femur; hemorrhages into the muscles of the left thigh; swellings about the opposite knee and both ankles; knee-joints normal; minute subpleural hemorrhages; well-marked exudative nephritis; minute hemorrhages on the surface of the liver. Case of Dr. W. P. Northrup. (The first autopsy in the United States.) Child of eighteen months; ill about one month. Autopsy showed subperiosteal hemorrhage of both tibiæ and both femora; detachment of the lower epiphysis of the left femur and maceration of lower end of shaft; bronchopneumonia of left lung; no rachitic or syphilitic changes on microscopical examination. Case of Dr. L. Starr. Child thirteen months; ill for three months. Autopsy showed "right leg from knee to ankle stuffed with a puffy mass replacing normal tissue. Separation of both bones one inch above ankle." Case of Dr. C. W. Townsend. Child of ten months; ill three to four weeks. Autopsy showed bloody serum in pleural cavity; perforating ulcer of the stomach; tubercular (?) process in peritoneum.

In conclusion the committee would thank publicly their correspondents who have sent their reports of cases and who are enumerated below. They are also much indebted to Dr. Wm. Schleif of Phiiadelphia for valuable aid in analyzing the circulars received and tabulating the result.

} Committee.

MINORITY REPORT.

1. From a study of this report and from due consideration of other known facts, scurvy appears to be a chronic ptomain poisoning due to the absorption of toxins.

2. It follows the prolonged use of improper food, and abnormal intestinal fermentation is a predisposing factor.

3. Sterilizing, Pasteurizing, or cooking of milk food is not, *per se*, responsible for the scurvy condition.

4. A change of food and the administration of fruit juice and treatment of any underlying cause is the rational therapeutic procedure in scurvy.

[SIGNED], AUGUSTUS CAILLÉ, M.D.

ACTION OF THE SOCIETY.

On motion, the majority report was adopted by the Society by a vote of 18 to 1.

WAR ARTICLES.

NEWS OF THE WEEK.

Two months have now elapsed since the war was declared and a brief retrospect of the results that have been attained by this country must prove satisfactory and instructive to every thinking man. Instructive especially are the results so far achieved as showing what can be done in a short time in transforming a quiet commercial and eminently intellectual people, resting quietly, in fact almost slumbering in the lap of peace, into a powerful recognized factor among the great fighting nations of the world. In the short space of two months another "great power" has been born and henceforth the United States must live outside of itself. The necessity for a navy has been forcibly and effectually taught us, and in the government of our newly acquired territory a large army of regulars must be hereafter maintained.

. . . . . .

Our Government has moved slowly but carefully, no serious blunders have been committed, and results so far are certainly satisfactory. Spain's navy is for the most part destroyed or safely entrapped awaiting destruction or capture; an army of nearly twenty thousand well-equipped men has been landed near Santiago de Cuba; another army of invasion is at hand to complete Admiral Dewey's capture of the Philippines; Puerto Rico is already in the shadow of another "army terrible with banners." Additional forces are on the way or ready to embark to each of these points and it is small wonder that the Madrid newspapers are urging plans for peace. And this is the result of the storm which came up out of a clear blue sky only two months ago!

. . . . . .

It is a cause for hearty congratulation that our army of invasion is safely landed on Cuban soil. A more helpless affair than a transport laden with soldiers on the high seas cannot well be imagined. A single torpedo-boat under cover of darkness might easily cause a destruction of life too horrible to contemplate. The landing of such a body of men on a hostile and almost unknown shore without wharfs is an undertaking of very serious concern and its safe consummation is most welcome news.

. . . . . .

The failure of the Army Board to supply veterinary surgeons for the cavalry troops has borne fruit in the shape of much influenza and a species of mania among the army horses. The latter ailment is quite new and little understood. At Tampa very many horses were affected owing to their being ex-

posed without shelter to the hot sun, the majority of them having been brought from Northern States, although as a matter of fact the southern-born animals were also unable to stand the blazing all-day sun to which they seem to have been exposed. The lack of veterinarians will doubtless receive ample attention as soon as possible.

. . . . . .

Every year when graduation time comes around the question arises, "What shall be done with the young physicians?" A plausible answer to this question which is yearly becoming more difficult to answer may be furnished by the war. Not only will our largely increased Army and Navy require many medical men, but our newly acquired territory will offer a field of lucrative practice for several thousand physicians, surgeons, dentists, and veterinarians.

. . . . . .

The advice that while Spain's communication with Cuba is entirely cut off our Government has secured direct cable service with Camp McCalla on Guantanamo Bay is most welcome news. The Washington authorities may now be kept fully informed as to the movements of General Shafter's army and of the ships of Admiral Sampson's fleets.

. . . . . .

It is hard to believe that Spain still retains as much of barbarism as is evidenced by her refusing to arrange for an exchange of Lieutenant Hobson and his brave comrades, and yet the indications are that she proposes to hold them as hostages. We trust due notice will be sent Admiral Cervera and Captain-General Blanco that they will be held personally accountable for the lives and health of these young heroes. On the other hand, as indicating a partly civilized condition of the Spanish, it is authoritatively reported that the bodies of the four marines who were killed in the Guantanamo fight were *not* mutilated as was at first thought. It is definitely stated by the surgeon who cared for the dead and wounded that the wounds which were attributed to mutilations were results of Mauser rifle balls.

PLUCK AND NERVE IN THE NAVY.

BY RAYMOND SPEAR, M.D.,
ASSISTANT-SURGEON, UNITED STATES NAVY, ON BOARD FLAGSHIP "NEW YORK."

BEFORE the beginning of hostilities with Spain when the ship's company was drilled in preparing the ship for action, the men all took their stations promptly, and each part of the machinery of the great engine of war was quickly manned, and in a very few minutes everything was ready for action. To an onlooker the quickness and precision with which each man took his station seemed marvelous. If these same people could see the actions of the same men when "general quarters" is sounded and there is reason to believe an engagement is imminent, they would scarcely believe their eyes. Now enthusiasm and spirit dominate everything. Each man knows that on the way his work is done depends in a measure the outcome of the conflict.

When everything is made ready, ammunition hoisted, guns loaded and manned, there comes a period of suspense, a calm before the storm, so to speak. Looking around the decks no sign of fear can be discovered; there are no pale or anxious faces to be seen, nobody seems to be thinking of home; every thought is for the present. Here and there the "jackies" are cracking jokes; the men at the guns that will be engaged seem the most contented of all; their companions on the unengaged side look sorrowful in comparison, and many a little oath is dropped by them about hard luck.

A period of expectancy now ensues. The nerves assume a state of tension, which is relieved as soon as the gun is fired. The crew now settle down to work. The first few shells from the enemy cause comment; when a puff of smoke from an opponent's gun is seen there are some that stop momentarily and watch for the destination of the shell, and feel relieved when they see a column of water rise out of the sea. When the first shell whizzes overhead almost everybody can be seen to duck. This is entirely a reflex act, and is no sign of fear. Soon all thought of the enemy's shells passes away, and the men at the guns have eyes for their own shells only. They know that the best defense is a well-directed fire. Each shot from the guns is noted, and when the range is accurately determined the Yankee marksmanship becomes evident.

At Santiago the shooting from the "New York" was wonderful in its accuracy, shell after shell being dropped exactly in the right spot, and the gunners and others sent up a shout each time a cloud composed of guns and dusty Dons arose out of a Spanish battery. The excitement of action for those who can see what is going on dispels any nervous strain that may have existed.

Below the decks, down in the engine and fire-rooms, in the coal-bunkers and magazines, there are many men working away, seeing nothing and hearing only the reports of the guns and exploding shells. If the engagement be with a ship they cannot tell at what moment a torpedo will come crashing in through the vessel's side, or if the ship be entering a harbor, at what instant the ship's bottom will be blown upward by a mine. These are the people

whose nerves are put to a strong test. But they never murmur, and so far no man in the American navy has given in to fear.

The action over, and the enemy's fortifications reduced, there is an air of satisfaction visible everywhere. Men can be heard discussing the different shots and talking about the target practice and wondering when they will get some more. When "secure" is sounded and "retreat" has gone, the men go about their duties as if nothing had happened. Looking around they can be seen writing, playing cards, reading, and sleeping quietly.

One of the best examples of the pluck and nerve in the American squadron was made manifest when a crew was wanted by Hobson to take the "Merrimac" into the harbor at Santiago and sink her in the channel. The fate of the men who were to go on the expedition seemed to be sealed, as the chances of getting through alive apparently were very slim. There was no call for volunteers; none was needed; for as soon as it became known that the "Merrimac" was to go in on its perilous trip, practically all of the officers and men in the fleet volunteered, and many were the disappointments when the seven heroes were chosen.

The war, so far as the Navy is concerned, has been devoid of many of its supposed horrors, and although the men have been on the larger ships for six months without getting ashore, there are few, if any, who would go home if they had the chance before the final battle is fought.

GETTING READY; FOREIGN MEDICAL MEN WITH THE UNITED STATES FORCES; A FLOATING HOSPITAL ON A SCOW.

Tampa, Florida, June 18, 1898.

To an anxious patient who was desirous of closing up his earthly affairs if his end was drawing near, the sagacious Flint, wishing not to unduly excite the apprehensions of the sick man, said to him, with characteristic tact, "It is better to be prepared and not go, than to go unprepared." This seems to be the principle on which the medical departments of the 5th and 7th Army Corps have been working for the past three weeks. We may never see Cuba but we are *getting ready to go.* Upon our preparedness will depend our efficiency as an organization when the "storm-and-stress period" sets in.

This "getting ready" constitutes a valuable field experience that we younger officers are acquiring and we may regard its acquisition as a priceless endowment. Organization has been the keynote of our activity since our advent at Tampa, and considering that we have been on a peace footing for more than thirty years it would be surprising did the wheels not creak a little. But the medical department will be found ready to go aboard the transports when the tocsin sounds.

Orders to prepare for early embarkation were given us on June 4th, since which time hurried preparations have been going on all along the line. The three divisional hospitals have been completing their organization, together with their ambulance-train service. The second divisional hospital, longest in existence, and therefore much encumbered with the sick and wounded has relieved itself by dispatching a carload of patients back to Atlanta.

Near this hospital on Tampa Heights is located the chief surgeon's office in the field. Here we had the pleasure recently of meeting a distinguished foreign medical officer, Brigadier-General Fr. Thaulon, Surgeon-General of the Royal Army and Navy of Norway, and President of the Norwegian Red Cross.

The general evinced much interest in the many phases of active field preparations that were going on, and remarked to us that Norway had had no war since 1814, implying perchance, in his tone of voice and gesture, that a too long-continued peace is apt to prove enervating.

We are happy in having with us also, Dr. A. E. Wynter, M.R.C.S., representing both the *British Medical Journal* and the *Lancet.* He is an old resident medical officer of St. Bartholomew's Hospital, London, and has had considerable experience with Indian fevers and tropical diseases.

Our volunteer and acting assistant surgeons are rapidly accommodating themselves to military methods. As remarked in your editorial columns, it is hoped that hints on medico-military topics will not fail to prove most timely and helpful to the members of the profession, inexperienced in military life, who are now going out with the volunteer forces.

These surgeons, are of course, well informed in regard to their strictly professional duties, but as to military methods or "red tape," as it is disparagingly termed, many of them are in the same situation in which a medical officer of the regular establishment finds himself on first entering the service. We have, therefore, a lively sense of sympathy for our brethren in this regard and stand ready to assist them in forming a proper conception of medico-military administration. The chief surgeon has in one or two instances assigned this duty to some of the medical officers of the regular establishment and those volunteer or acting assistant-surgeons inexperienced in military matters have shown great zeal in acquainting themselves with army methods.

Volunteer stewards are being instructed in the

making out of official records and reports of the medical department in the field, and inasmuch as these papers pass for revision and signature through the hands of commissioned medical officers it would show a commendable zeal in the latter to acquaint themselves with the provisions and requirements of the manual for the medical department, and those paragraphs of army regulations which relate to the medical department, as well as certain chapters in Smart's "Handbook for the Hospital Corps," and the printed directions upon the required reports themselves. Add to these the drill regulations for the hospital corps and circular No. 3, issued from the Surgeon-General's Office, Washington, D. C., May 18, 1898, giving a summary of the duties of chief surgeons of corps, of divisions, of brigades, of regiments, of division hospitals, and of ambulance companies, and the student will not remain long uninformed of his rights and duties.

Those who have acted as local sanitary officers on boards of health may have already acquired that alertness and eternal vigilance so requisite in an efficient sanitary officer, otherwise they may do well to cultivate the habit of inspecting their sanitary surroundings and by rendering a strict account of unsanitary conditions to their immediate commanders, exonerate themselves from any blame attaching thereto. Upon first joining the service it is incumbent upon the young medical officer of the regular establishment to become thoroughly conversant with the making of reports and records required by the medical department. Of course, he has a steward or acting steward, but without any disparagement of this very efficient branch of the medical organization, efficient administration of a military hospital requires a commissioned medical officer competent to direct and review the work of his assistants.

A plan for a floating hospital on a scow has been evolved by Captain Euclid B. Frick, Surgeon attached to the Battalion of Siege Artillery. While serving at Port Tampa he noticed some scows floating in the bay and he set himself to considering the feasibility and advantages of erecting hospitals upon these platforms. He has made drawings and submitted them to the chief surgeon.

His proposition is to take a scow 90 x 30 feet, having a landing platform in front 10 x 30 feet, and locate upon the lower floor of a two-story structure a dispensary and office, ward for twenty men, quarters for twelve members of the hospital corps, quarters for surgeon and assistant-surgeon, store-room, water-closets, and bath-rooms, and on the upper floor, operating-room, four small rooms for treatment of officers, officers' dining-room, dining-room for enlisted men, kitchen, quarters for three hospital stewards, and a ward for twenty-one patients. Two force pumps are provided for water-supply, one on the right and one on the left of the landing platform. The one on the right forces salt water to the salt-water tank on top of the house for use in flushing closets. The one on the left forces water to the fresh-water tank on top of the building from a small tank supply-boat for general use. The advantages claimed are: The location is cooler; no dust, so prevalent at Tampa; no trouble with drainage and sewerage, and the floating hospital is away from centers of local infection. It could be anchored in Tampa Bay where the water is smooth and if needed could be towed to distant parts. When the war is over, the structure could be utilized as a place of detention.

HENRY I. RAYMOND, M.D.,
Captain and Assistant-Surgeon, United States Army.

MEDICAL PROGRESS.

Study of Epilepsy and Its Treatment by Resection of the Cervical Sympathetic.—SCHAPIRO has written a monograph upon the above subject, of which an abstract appears in the *Centralblatt für innere Medicin*, May 21, 1898. Epilepsy is in the highest degree a chronic disease, which almost never subsides when once it is firmly established. It is a neurosis which in its early stages has no demonstrable anatomical basis. The numerous and varied changes in the cerebrospinal system which often accompany it are to be looked upon as secondary. Also the changes of the cervical sympathetic are not constant enough to be regarded as an anatomical basis of the disease. Whatever the *primum movens* may be, which upon hereditary or acquired grounds calls forth epileptic attacks, the immediate cause of a particular seizure lies in the vasomotor system, and consists in a sudden cerebral anemia, followed by a passive cerebral congestion, in consequence of paralysis of the vasomotor center. This theory explains all the clinical phenomena. The true epileptic aura described by Brown-Séquard is seldom seen. The exciting cause may be either peripheral or central, but in either case it acts upon the vasomotor center.

The resection of the cervical sympathetic ganglia produces a very sullen and severe cerebral anemia, and increases the vitality of the nervous elements of the brain. It is sufficient to remove the upper and middle ganglia and the cords which unite them. The operation is not at all dangerous. A myosis is the only permanent change which follows. Still the shrunken pupil reacts very well to light and accommodation, and dilates readily again under the influence of atropin. The results thus far obtained encourage one to make further attempts, especially in the case of those epileptics who, in spite of all non-surgical measures, suffer from an increasing frequency of attacks.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

CARE OF THE SOLDIER'S FEET.

A FEW weeks ago we called attention to the fact that by far the most essential requisite of a soldier's outfit is a properly constructed, well-fitting shoe. We pointed out that the method of awarding contracts for footgear to the lowest bidder was bound to bring forth a very undesirable article unless the closest watch was kept upon the various contractors. It seemed to us then, as it seems now, that it would be the right sort of economy to place the contracts with the most reliable manufacturers and pay them a price which would permit them an honest profit. Already complaints are finding their way into the public press. In the *New York Herald* of last week Colonel R. E. Leonard of the Twelfth New York Volunteers is made to say: "If I were asked what I had to complain of I could only say that the Government shoes are of poor quality and do not wear." This has been a complaint of commanders dating back to the time when shoes were first adopted as footgear. Although the Commissary Department cannot be made to realize the immense importance of providing the right sort of boots, and although there may be obstacles in the way of obtaining them, much can be done by the medical personnel of the various divisions of the army in keeping in good condition the feet of the soldiers under their care.

In a recent issue of the *Deutsche mil. artz. Zeitschrift* there is an article by Gerdeck on the use of formalin in the care of the feet of troops which contains many timely suggestions that may be utilized for our own soldiers. When a concentrated solution of formalin is applied to the feet a few times, the feet do not sweat again for two or three weeks, even though woolen socks are worn. He recommends that undiluted formalin be penciled over the feet three or four times at intervals of about six hours, and that four or five drops of the same fluid be dropped into the boot to disinfect it and to protect the leather. Thus applied it is not only a prophylactic but it enables soldiers who habitually suffer from sore feet to march without difficulty. Even though the feet be blistered it hardens the softened tissue and makes walking painless. The writer holds that it produces no constitutional or local destructive effect. If his claims be true, and theoretically they seem quite plausible, it behooves Surgeon-General Sternberg to provide his department with the facilities for utilizing a measure which can give so much comfort for a trifling outlay. Next to profound derangement of his alimentary canal, there is probably nothing that destroys a soldier's morale more completely than sore feet. If they can be kept intact by the use of formalin as described by Gerdeck, this author becomes the soldiers benefactor and legions of them will call him blessed.

DRUGGISTS AND DOCTORS.

IF there is a subject of more than ordinary interest to the followers of medicine and pharmacy it is the relation which exists between them in connection with the writing of prescriptions, counter-prescribing, and the dispensing of medicines by the physician himself. There is scarcely a prominent druggist in any large city who is not ready to pour out his tale of woe to the effect that both in the country and in the city physicians are daily prescribing, more and more frequently, directly for their patients without calling in his pharmaceutical aid. The average physician, on the other hand, is loud in his complaint that pharmacists are continually prescribing for persons over their counters and thereby preventing the physician from receiving the fee for medical

advice to which he is entitled. Because of the fact that large manufacturing concerns place medicinal preparations ready for dispensing in the hands of physicians these manufacturers are regarded with a jealous eye by the retail pharmacist.

The questions we have raised are of vital importance, particularly to the druggist. At a recent meeting of the County Medical Society in Philadelphia a number of druggists who were asked to be present, urged upon the members of the Society that they should prescribe compound remedies, the formulæ of which are given in the publication known as the "National Formulary," and an evident endeavor was made to wean physicians back to the old habit of writing "shotgun prescriptions" for every patient. There is a good deal to be said on both sides of this subject, and one's point of view depends largely upon the question as to whether he is a physician or a druggist. There is certainly no objection whatever, except the personal interest of the druggist, to the physician dispensing well-made medicinal substances to his patients. On the other hand, aside from business reasons, there are very grave objections to the druggist prescribing for patients over his counter; for in the latter instances there is lacking that knowledge which is necessary for the proper treatment of disease, while in the former case the pharmaceutical side of the question has been attended to by the manufacturing chemist before the drugs pass into the physician's hands.

As if for the purpose of carrying the war into Gaul, the Philadelphia College of Pharmacy has recently decided to confer the degree of Doctor of Pharmacy upon its graduates, having found, apparently, that the old-fashioned title, Graduate in Pharmacy, is not suitable for this advanced age in which even patent-medicine venders and chiropodists are entitled to the title of Professor.

The recent conferring of the degree of Doctor of Pharmacy by this College upon a large body of graduates has called forth an amusing criticism upon the part of the *Medical Press* and *Circular* of London, in which after sadly deploring the disgrace into which the terms Professor and Doctor have fallen the editor calls attention to this recent action in Philadelphia "in which eighty-seven students of pharmacy received the degree of Doctor in Pharmacy with a pretty hood, the subject of examination being compounding medicine and wrapping up bottles." While we cannot subscribe to the subsequent caustic but unbecoming comments of the editor, we confess to a feeling of wonder as to what class of men are next to receive the honorable title of Doctor.

ECHOES AND NEWS.

The Unsanitary Oath Abolished in Maryland.—The form of the judicial oath in Maryland has been simplified, and the "kissing of the book" has been abolished.

Appropriation for Johns Hopkins University.—The Maryland State Legislature has appropriated $400,000 to this institution to tide it over its financial straits, due to the loss sustained in the default of the Baltimore and Ohio Railroad.

Birds to Produce Tuberculosis Antitoxin.—Professor E. Behring claims that he has discovered a method of avoiding the injurious after-effects of horse and other animal serum, to which consumptives seem particularly sensitive. He substitutes the serum of birds.

New York Hospital Improvements.—In addition to the proposed $300,000 annex to the New York Hospital building, further improvements are to be made. These include a six-story ambulance and laundry building to cost $90,000, a two-story governor's building to cost $80,000, and alterations and repairs to the present hospital building which will cost $30,000, making a total of $500,000.

Officers of the American Association of Genito-Urinary Surgeons.—At the meeting of this Association, held at Cranston's Hotel, West Point, June 7 and 8, 1898, the following officers were elected for the ensuing year: President, Dr. James Bell of Montreal; vice-president, Dr. Samuel Alexander of New York; secretary and treasurer, Dr. Wm. K. Otis of New York. It was decided to hold the next meeting at Niagara Falls, in May, 1899.

Honorary Degrees To Be Conferred on Medical Men.—At the International Zoological Conference, to be held in Cambridge in August, the honorary degree of D.Sc. will be bestowed on Dr. Henry P. Bowditch, Professor of Physiology in the University of Harvard; Dr. Camilio Gogi, Professor of General Pathology in the University of Pavia; Dr. Hugo Kronecker, Professor of Physiology in the University of Berne, and Dr. Willy Kuhne, Professor of Physiology in the University of Heidelberg.

University of Vermont.—At the meeting of the Faculty of the Medical College of the University of Vermont, held June 22, 1898, Dr. A. P. Grinnell was retired from the office of dean, which office he has held for the past twenty-four years, and Dr. H. C. Tinkham of Burlington, Vt., now occupying the Chair of Surgery and Anat-

omy at the College, was elected his successor. It is reported that the medical students of the college have protested against the action of the Faculty in removing Dr. Grinnell.

Deaths from Diphtheria and Croup in New York City.—The following statement announced by the Board of Health shows the steady decline in the number of fatal cases of diphtheria in the Buroughs of Manhattan and the Bronx during the first twenty-four weeks of each of the following years: 1894, 1657; 1895, 1090; 1896, 1122; 1897, 913; 1898, 524. Deaths from diphtheria during the week ending June 4th, 10. For the week ending June 11th, 9. Corresponding weeks of last year, 37 and 39 respectively.

Illness among Naval Officers.—It is said that the hospital ship "Solace" will bring home on her next trip a number of naval officers who have succumbed to the strain and have been obliged to give up. The officers on monitors suffer most because of the terrific heat below decks, although the battle-ships and cruisers are not much cooler. On board the monitors the heat in the engine rooms reaches 160° F. and is never below 125° F., and the temperature of the apartments in which the officers sleep is usually about 110° F.

Resolutions of Thanks to the Late Professor Page.—At the end of the winter course of instruction in Physical Diagnosis, given to the students of the New York Polyclinic by the late Professor R. C. M. Page, the students passed resolutions extending to Professor Page their sincere thanks for the kind, courteous, and able manner in which he had conducted the class, and tendered him their best wishes for his continued success and happiness, with the hope that his teachings and the principles set forth by him might be handed down to future generations of all who desire a thorough knowledge of medicine.

A Strange Hallucination.—A report is going the rounds of the secular press, and has also found its way into some prominent medical journals of the country, announcing that Dr. Simmons had met with a serious accident while operating recently at the New York Polyclinic Hospital. The authorities of the Polyclinic Hospital announce that no surgeon by that name is now or ever has been connected with that institution. Moreover, that no such accident as described has occurred in that hospital; in other words, the whole story is a hoax, and must have been evolved from the inner consciousness of some dreamer.

Changes in the Faculties of the New York Medical Schools.—Drs. Austin Flint, Frederick C. Dennis, and Samuel Alexander have resigned their positions in the Faculty of the New York University Bellevue Medical School, and have accepted like positions in the Faculty of the Cornell University Medical School. Their places in the former institution have been filled respectively by Dr. Graham Lusk, Professor of Physiology; Dr. B. Farquhar Curtis, Professor of Clinical Surgery, and Dr. L. Bolton Bangs, Professor of Genito-Urinary Surgery. Dr. Christian A. Herter has also been appointed Professor of Pathological Chemistry in the same institution.

The Claims of Osteopathy Exposed.—The secretary of the Illinois State Board of Health, Dr. J. A. Egan, announces in a circular letter over his signature that the assertion made in a circular issued by a concern in Chicago claiming to teach the alleged science misnamed osteopathy, is a lie in the fullest acceptation of the term. This institution advertised that its "Terms of study are so graded and the courses of study so broad and complete, that they comply with all the requirements of the Illinois State Medical Board, and allowed our students two-years' credit on the regular medical education. These credits are recognized in any medical college in this country, and will be equivalent to two-years' work done there." Dr. Egan also declares "It is not true that the 'credits' named are recognized in any medical college in this country."

CORRESPONDENCE.

LETTER FROM GLENWOOD SPRINGS, COL.

[Special Correspondence of the MEDICAL NEWS.]

THUS far has the medical host advanced into this friendly country, and although many individual trips beyond this point have been planned, Glenwood Springs is the Ultima Thule of the representative multitude. And a worthy objective point and a delightful resting-place it is.

The determining factor in selecting Denver as the place of meeting of the American Medical Association, and the attractive scientific feature of the brief sojourn of the members themselves, was the opportunity afforded of securing at least a baptism in the brilliant sunshine and rarified air of Colorado's vaunted climate. This, however, was not afforded during the three days in which the Association was in session. The weather of this favored clime seems to be determined with the regularity of clockwork. Statistics show that for twenty years the first week in June has been wet and rainy. This year afforded no exception, and every afternoon brought its thunder-shower. But to those who tarried for the various excursions an opportunity was afforded of experiencing all the glories that had been anticipated. The air is clear and transparent, the sunshine bright and even hot, and an invigorating quality is in every inhalation. The two markedly noticeable qualities of the air are rarity, occasioned by the altitude, thus facilitating expansion of the lungs, and dryness. The city of Denver is just one mile above sea level; its air is sufficiently rarified to be painfully apparent to many of the visitors upon only slight exertion, resulting in palor of countenance and sighing respiration. This gradually wore off as the days advanced.

Living witnesses to the health-giving qualities of the climate were on every hand. Every one with whom we conversed, from the judge on the bench to the cab-driver at the railroad station, originally came to this country to recover from the ravages or the invasions of tuberculosis. In local parlance they are all "one-lungers." With

one notable exception, all the medical profession of Denver belong to that class, and yet, as a rule, a browner, better nourished, more vigorous body of men would be difficult to find in the medical profession of any community. No greater error, however, could be entertained than to infer that every phthisical patient who comes here is cured. One of the delegates, a doctor from Pennsylvania, sadly confessed that Colorado climate had failed to cure his daughter, and after a trial of four years, he was compelled upon his return to take her home with him, a hopeless invalid. Many similar experiences could be narrated. Indeed, it is an accepted principle that only those phthisical patients who are in the incipient stage can hope for benefit by a residence in Colorado. Of the latter class, striking demonstrations of the prompt and curative effect of the climate are to be met, with surprising frequency. At Colorado Springs a young man from New York had, after three-weeks' residence, gained two and a half pounds in weight, and recovered entirely from the periodical rise in temperature and night-sweats from which we saw him suffering at the time of his departure from sea level four weeks since.

To an invalid who cannot participate in any physical or mental effort, the expense of living in a chosen locality is an important one, and in Colorado living is expensive. The economic law that prompts the farmer to send all his best products to market applies to Colorado, and the bountiful supply of milk and beef, which promptly suggests itself to the would-be sojourner here, vanishes upon the presentation of the check for his first meal. The small farmer has learned long since that he cannot compete with the great ranchman, and does not try, and all the products of the great ranchmen go to the Eastern markets in wholesale routine fashion. Indeed, one of the Denver physicians remarked in conversation that if he wanted an especially fine piece of beef for his table it must come from Chicago. That, of course, means expense. At Colorado Springs rents are high and table-supplies costly. The result is that only those who have abundant means can secure the nourishment they need, and the less favored ones who go there for their health are in danger of languishing sooner or later in some ill-kept, poorly-supplied boarding-house. One redeeming feature of this condition is that a man, as soon as he is strong enough, can usually find some out-of-door employment. What opportunities of this character are open for women did not develop.

A recent comer remarked, "For a man of financial means, who is afflicted with phthisis, this country is a perfect paradise. He has the consciousness of feeling that he has placed himself in the best possible environment for his recovery, perhaps the satisfaction of knowing that he is steadily improving, and has within easy access numerous points of inexhaustible interest to beguile his time." And all this is true as we have had abundant opportunity of observing in the many delightful excursions which have been made to the various cañons, mining-camps, and mountain-tops. The beauty, the grandeur, the inexhaustible mineral wealth of these Colorado mountains are features that impress one at every turn. But no pen or brush can do them justice. They must be felt and allowed to sink into the mind and soul to work their grand and ennobling influences. The climax of excursions was reached in the full day trip over the Midland Railroad amid ever-increasing grandeur of mountain scenery, including the Hagerman Pass over the continental divide of the Rockies, from Colorado Springs to this inviting health-resort. But the natural attractions of Glenwood Springs and the curative qualities of its healing waters must be left for a future letter.

JUNE 15, 1898.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

RESIGNATION OF THE PRESIDENT OF THE COUNTY MEDICAL SOCIETY—REPORT OF ORTHOPEDIC CASES—NEURASTHENIA IN RELATION TO GYNECOLOGIC CONDITIONS — GRADUATION EXERCISES OF THE PENNSYLVANIA DEAF AND DUMB INSTITUTION—PENNSYLVANIA PHARMACEUTICAL ASSOCIATION—PERSONAL NOTES—PROFESSOR STEPHENS' ARREST—HEALTH-BOARD STATISTICS.

PHILADELPHIA, June 28, 1898.

AT a meeting of the Philadelphia County Medical Society, held June 22nd, the resignation of Dr. Edward Jackson, President of the Society, was read and accepted. Dr. Jackson leaves the city to reside permanently in Denver, Colorado. Dr. S. Solis-Cohen, first vice-president, will conduct the meetings during the rest of the year as vice-president, for, if elected president during this term, he would be debarred from again acting as such.

Dr. James K. Young exhibited a number of cured orthopedic patients who had presented lesions of the spine, knee, and hip-joint. Among the number were two cases of arthritic hip-disease with recovery so complete as to enable them to show the three so-called "test positions." Another case, that of a man with tuberculosis of the elbow-joint, showed a remarkably good result from treatment by fixation and injections of iodoform.

Dr. J. M. Fischer presented a specimen from an ectopic gestation, which, he said, was the fourth he had had in the last month or so. So many similar reports are heard on every side that it brings up the question of the cause for the increase of this condition; either physicians have improved in their diagnoses or the ever increasing number of gynecologic operations is bearing fruit.

Drs. F. Savary Pearce and H. D. Beyea presented a paper on "Neurasthenia; Its Relation to the Physiology and Pathology of the Female Generative Organs." Dr. Pearce, who read the paper, believes that there is an intimate relation between the nervous condition of a patient and the condition of the uterus and its appendages; that gross lesions produce neurasthenia less often than do mild ones; that gynecologic conditions are the chief factors in the causation of hysteria, epilepsy, and insanity. He believes that some cases of neurasthenia are essential and not sympathetic, however, and advises in all cases treatment of the nervous condition *per se*, as well as the local treatment, whatever it may be. Dr. Shoemaker believes that it is a common mistake for the gynecologist to ignore treating the nervous condition and for the neurologist to

ignore the gynecologic treatment; he believes in a combination of the two and above all absolute rest.

Dr. Faries quoted from his personal experience two cases of insanity in which the patients were operated upon for gynecologic conditions. In one case reason was restored, while in the other there was no benefit though the cases were identical. This experience leads him to believe that we are still groping in the dark as to the relation of nervous phenomena to pelvic disturbances.

Dr. Fischer said he believed there were some cases of essential neurasthenia associated with gynecologic conditions but he would like to know how to distinguish these cases from sympathetic neurasthenia. Dr. Eshner claimed the environments of the patient and her previous health are the diagnostic guides in these cases.

Nineteen new members were elected, after which the Society adjourned until its next meeting, September 14th.

The graduation exercises of the Pennsylvania Institution for the Deaf and Dumb, at Mt. Airy, were held on Tuesday, June 21st. They were of unusual interest, because during the past year a large number of pupils have acquired the power of articulation, and some the complete power of speech. Owing to the illness of Dr. John H. Brinton, Miss Morris distributed the prizes in place of Mrs. Brinton, who takes a good deal of interest in this work for the deaf and dumb.

The Pennsylvania Pharmaceutical Association held its annual meeting at Waynesboro, June 23d. Dr. Joseph P. Remington of Philadelphia read a report of the work accomplished by the International Association of Pharmacists, held at Brussels, to which he was delegate from the United States. The following officers were elected: President, M. N. Kline, Philadelphia; vice-presidents, Louis Emanuel and D. J. Thomas; treasurer, J. A. Miller; secretary, J. Lemberger.

Dr. William H. Wells, now Adjunct Professor at the Philadelphia Polyclinic, has been appointed Instructor in Obstetrics at Jefferson Medical College.

Dr. J. H. Musser has returned from Maryland, where he read a paper on "Heart Disease" before the Tri-State Medical Association of Western Pennsylvania, Western Maryland, and West Virginia.

Dr. S. Weir Mitchell, contrary to his usual custom, will not go abroad this summer, but will stay at Bar Harbor.

The local Red Cross Society raised a large amount of money this week by an entertainment at the Academy of Music, which consisted of historical tableaux.

The arrest and subsequent confession of George H. Stephens, last year a professor in Lafayette College, has interested the medical men of Philadelphia this week. From the burning of Pardee Hall last December unti his arrest, Stephens has perpetrated a series of acts which it is hard to attribute to a man supposed to have any moral responsibility. These deeds of vandalism were a part of his plan of revenge for having been dismissed from the college for inefficiency last year, and now that he is arrested no doubt money will be used lavishly to prove him mentally irresponsible, for he is well connected and his relatives are wealthy—an opportune time for the "expert" to step in.

The total number of deaths in this city as reported at the Health office for the week ending June 25th, was 387, of which number 152 were of children under five years of age. There were 177 new cases of contagious disease reported, as follows: Diphtheria, 63, with 12 deaths; scarlet fever, 23, with 1 death; typhoid fever, 91, with 7 deaths.

Saturday ushered in the usual summer victims, fifteen prostrations from heat being reported.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

WANDERING TROUPES OF FOREIGNERS AND CONTAGIOUS EXANTHEMATA—SMALLPOX IN BERLIN—PROFESSOR SENATOR ON VARICELLA AND VARIOLA AND THEIR RELATION TO EACH OTHER—GERMAN OPINIONS, POPULAR AND MEDICAL, AS TO THE HISPANO-AMERICAN WAR.

BERLIN, June 18, 1898.

A TROUPE of negroes from Koto, one of the German South African Colonies, has been on exhibition for some time at one of the museums in Berlin. An exanthematous disease made its appearance among its members that for some days puzzled the diagnostic ability of the German physicians unaccustomed as they are to seeing eruptions on dark skins. The affected ones were promptly segregated, however, even before the diagnosis was assured, and the result justified the precautions since the affection turned out to be smallpox. Among the troupe so far some fifteen cases have occurred, the first time that so many cases have been in Berlin in many years. How little solicitude the occurrence of the disease has evoked may be judged from the fact that Professor Senator invited his class, consisting of more than 100 students, to come with him to the Institute for Infectious Diseases to see and study with him a case under his care there. No special precautions were taken and students were allowed to approach and see and even feel the lesions. Those who had not been vaccinated within recent years were warned of their danger and advised not to come. Evidently the Germans have unbounded faith in the value of vaccination, and the statistics of Berlin since the enforcement of the universal vaccination requirements would seem to justify them, for, as I have said before, Berlin's mortality and morbidity from smallpox compared to that of Paris, where vaccination is advised but not required, is practically *nil.*

These wandering troupes of people from lands where vaccination is unknown are always the subject of special watchfulness as regards smallpox outbreaks here in Germany. The well-known liability of the disease to spread to all the members of the troupe and to occur in the severer forms which are scarcely ever seen any more in Europe has been often a subject of remark. Whether these people have a special liability owing to their being a virgin soil or whether the Europeans after generations of vaccination have acquired a certain constitutional resistance to the disease is not clear. Certain it is that the wandering of such people is considered to constitute a special source of danger in the carrying about of virulent

forms of the disease and in their liability to contagion on the slightest exposure when Europeans escape entirely. A troupe of Eskimos wandering through Europe on exhibition some years ago were all carried away by smallpox.

The day before Professor Senator received his first case of smallpox he had some cases of varicella, ordinary chickenpox, in his polyclinic, *i. e.*, dispensary or out-patient department. In the course of his talk on the disease he said that he had for years held Heberden's opinion that varicella and variola are entirely distinct and independent diseases. He stated very forcibly the reasons for holding such an opinion, especially insisting on the failure of varicella to immunize against variola and on the failure of vaccination to protect against varicella and then added that notwithstanding all this he had come to believe in these later years that Hebra's opinion, that the two diseases are identical, varicella being only a very mild form of variola, is the correct one. He says that he has noted a number of times in his polyclinic (out-patient) work here in Berlin (he has an immense out-patient service), that whenever there was an epidemic of varicella among the children he would either know of or hear shortly of some cases of smallpox having occurred in the city and usually in the quarter of the town where the smallpox had been found. At the moment he said he knew of no smallpox cases in town but he would not be surprised to hear of them. The opportunity to show the smallpox cases to the class occurred next day when he recalled what he had said the day before. Under the circumstances the incidents were calculated to produce a most lasting impression.

Senator considers that generations of vaccination and the intermixture of elements rendered immune to smallpox because the progenitors had had the disease, have lessened susceptibility to the virus of the disease to such an extent that this larval and abortive form is the result of an infection that under other circumstances would be true smallpox. That the slight reaction of the organism to the disease should not be sufficient to produce that profound tissue change which constitutes immunity to the disease in a virulent form does not seem surprising. The virulency of the affection is so slight in its masquerade form of varicella that as a rule only children are affected by it, the more vitally resistant adults escaping it.

The Vienna Dermatological School have always continued to hold Hebra's opinion in the matter despite the almost universal acceptance of the great English clinician Heberden's opinion by the rest of the medical world. Kaposi still teaches it though it is a matter of genuine surprise to hear of an old experienced clinician like Senator being converted to an opinion that seemed to still have a place in medical literature only because a great man's school did not care to give up the favorite teaching of their great master. As Senator says, only the discovery of the cause of the two forms of disease can settle the question.

Of course the Spanish-American war is the great subject of present interest even over here. Almost naturally one would say German popular opinion has been in favor of the weaker of the combatants to the no small annoyance of the resident Americans. At several of the universities there have even been public protests on the part of American students against the unjust light in which American interference in the Cuban question has been placed. Another thing that has been a source of considerable annoyance has been the immediate acceptance by German newspapers of the reports of war operations emanating from Madrid. American newspaper accounts are always scouted as either fictitious or exaggerated, while Spanish information was looked upon as authentic. They have not learned to properly discount Spanish war news, for as very little attention has been paid to the Cuban insurrection they have known nothing of the training acquired by the Spanish authorities in this matter.

Only the German medical men have, I think, realized to some extent that the war is not one of conquest nor dictated by lust of dominion but is a nation's protest against the further oppression of a long-suffering people. Their comprehension of the true state of affairs, defective though it is, is a pregnant sign of that broad-minded sympathy with humanity that characterizes the profession the world over and that is drawing into closer brotherhood the elements in modern social life whose purposes are the good of humanity and the relief of suffering under all circumstances. Meantime, as it has become clearer that the war is not to last so long after all, and success has attended the American arms, German sentiments are materially changing. People who worshiped the Setting Sun have been remarkably few in history, and the Germans are least of all likely to care to be of the number. A comic paper cartooned German public opinion at the beginning of the war as a prophetess unable to see who was to be the victor in the conflict, but able to foresee one thing very clearly, that whoever would be the victor would receive a telegram of congratulation from Berlin. *Ridentem dicere verum, quid vetat?*

TRANSACTIONS OF FOREIGN SOCIETIES.

Berlin.

THE CURATIVE ACTION UPON FIBROMYOMATA OF LIGATION OF THE UTERINE ARTERIES—USES OF IODVASOGEN—VENESECTION IN CHILDREN.

GOTTSCHALK read a paper before the Medical Society, March 30th, on "The Curative Effect of Ligation of the Blood-vessels upon Uterine Fibromyomata." Rydygier carried out this idea by performing laparotomy, but it did not find much favor, for the reason that it was almost as dangerous as the removal of the growths. The vaginal operation, however, is absolutely without danger, and is carried out as follows: After curettement a transverse incision is made around the cervix, the bladder is pushed back from the vagina and broad ligaments, and the posterior vaginal vault is also pushed away from the broad ligaments, until the ligament containing the uterine artery on either side is freely exposed. This is ligated as close as possible to the uterus by three interlocking ligatures on each side. In this manner not only the chief artery, but its adjoining branches, are included in the ligatures. The peri-

toneal cavity is not opened. The ligatures are then cut short, and the incision in the vaginal vault is sutured. Twenty patients operated upon by this method all recovered. The operation is often followed by rather severe pain, which may have to be controlled by morphin. This lasts only a few days, and the patients are up and about in ten days. In nineteen of the twenty cases there was present obstinate hemorrhage, which medical measures and curetting had failed to relieve. In all cases except one the bleeding stopped at once, and did not recur. The strong pains which are produced by the ligation of the blood-vessels crowd intramural myomata, either within the uterus, where they may be expelled, or outside of its muscular coat, where as subserous tumors they give rise to no more trouble. This explains why the operation fails to give relief in hemorrhage associated with the menopause. In fourteen of the patients treated by this method the tumors had palpably shrunk, while in seven they were no longer to be made out.

DUHRSSEN advocated in place of ligation of the arteries the method of Sneguireff of bringing live steam into the uterine cavity. By this means, without operation, without narcosis even, in three minutes the lining of the uterine cavity is completely destroyed, and all possibility of a recurrence of hemorrhage is thereby removed. In young persons the application of the steam is made very short, so that the mucous membrane is shriveled, but not entirely destroyed. This treatment has proved efficacious in a long series of cases, and seldom has it been necessary to repeat it.

In reply Gottschalk said that vaporization is at best a symptomatic treatment, as it does not remove the myomata nor cause their atrophy. Moreover, it destroys the function of the uterus as a child-bearing organ.

At the session of May 4th, FRIEDLAENDER spoke of his experience with iodvasogen, an oxygenated vaselin containing six per cent. of iodin, and which he had used externally in eighty-one cases, and internally in fifty-one cases. Some of the cases in which cures resulted from external application were old ulcers, scrofulous eczema, eczema capitis, periostitis, ulcer of the cervix, pleuritic pain, and obstinate bronchitis. To most of the patients the remedy was also administered internally. It failed to give relief from the pains of neuritis, flatfoot, and chronic rheumatic arthritis. Its internal administration was successful in goiter, pleurisy, rheumatism, scrofula, syphilis, and bronchitis. It failed in whooping-cough, chronic rheumatoid arthritis, advanced Graves' disease, arteriosclerosis with asthma, phthisis, and cardiac diseases. The effect of iodvasogen in improving the appetite was striking. It also allayed vomiting of pregnancy. The dose when given internally, was from 5 to 30 drops, in milk, tea, or coffee, three times daily. Externally, from 10 to 30 drops were rubbed into the skin three times a day. Its absorption is shown by the presence of iodin in the urine within two or three hours after the application of the iodvasogen. Externally it is much better borne than tincture of iodin.

BAGINSKY read a paper on "Blood-letting in Children," in which he regretted that for the last twenty years text-books on diseases of children have ignored venesection and leeches. He gave the details of three cases to show that the abstraction of three or four ounces of blood had saved the lives of one child suffering from badly compensated heart-disease, and of two others cyanotic from chronic bronchitis. In other patients venesection was followed by an improvement which was only temporary, because the organism, although freed by the blood-letting from the mechanical obstruction to circulation, had not sufficient power to overcome the intoxication of the disease itself. Owing to the difficulty in finding and opening a vein in a child, it is better to divide the skin and dissect the vein free before opening it. Baginsky also advocated the application of leeches to children suffering from eclampsia, whether simple or uremic. In simple spasms the use of other remedies, baths, douches, choral, chloroform, bromids, etc., is generally sufficient to cure the trouble. Nevertheless, that the abstraction of blood from the head by leeches will give prompt relief, is no cause for surprise when one remembers how distended the visible cerebral vessels are under these circumstances. And if this is true of simple spasms, how much more so of uremic convulsions.

Vienna.

NEW METHOD OF MEASURING THE VOLUME OF THE LUNGS—DILATATION OF THE CYSTIC END OF THE URETER—NEPHRITIC INDICATIONS OF OBSTIPATION—TREATMENT OF LUPUS WITH HOT AIR—RECURRENCES OF MALIGNANT TUMORS AT LONG INTERVALS — REDUCTION OF A STRANGULATED HERNIA A CAUSE OF INTESTINAL OBSTRUCTION—CAUSES OF DEATH FROM DIPHTHERIA BEFORE AND AFTER THE USE OF SERUM.

BASCH demonstrated a new method of measuring the volume of the lungs before the Imperio-Royal Society of Physicians, April 22d. This method is based on Mariotte's law of the relation between the volume and pressure of any given quantity of gas. If the volume of gas which it is desired to investigate be reduced by pumping other gas into the chamber, until a certain pressure is obtained, its amount can be estimated by pumping the same amount of additional gas as was added in the first case, into a receptacle of such a size that the same pressure will be obtained. To apply this method to the lungs this test-receptacle must be elastic and of about the same power of resistance as the lungs. The pressure is obtained with a mercury manometer, and the air is pumped into the lungs through a tube fitting tightly into one nostril, while the other nostril and the mouth are tightly closed. Tests upon dogs, which were afterward confirmed by the removal of the lungs, showed the accuracy of this method of estimating the pulmonary capacity.

ENGLISCH spoke of pouched dilatations of the cystic end of the ureters, and showed a specimen from a patient aged thirty years, who was greatly troubled with cystic tenesmus with enlargement of the prostate, though with little residual urine. The amount of sediment varied greatly. No definite tumor could be felt in the region of the kidney or ureter, though there was a feeling of greater resistance over the lower portion of the urete rof

the right side, and tenderness. Pressure on this region, as shown by cystoscopic examination, caused the escape of urine in a small stream. The patient refused operation, and died in a short time. The pelvis of the right kidney was found to be much dilated, while the whole ureter was as large as the small intestine, and presented at its lower end a large pouch-like formation, which extended to the middle lobe of the prostate. The opening itself was very small.

There have been recorded in medical literature thirteen cases of similar trouble, most of them occurring in women. If the pouch is a small one it may extend like a hernia into the bladder, or even into the urethra, where in women it has even been visible at the external orifice. Pressure in the renal area will make the cyst grow tense, especially if the opening into the bladder is closed. The anomaly has usually been looked upon as congenital, and it is so regarded by the speaker, who attributed the formation of a pouch to the presence of adhesions in the walls of the ureter, as is seen in other tubes.

KOBLER discussed the nephritic symptoms due to obstipation. In Sarajavo he had an opportunity to observe many cases of dysentery, and in the period of obstipation which followed the diarrhea, symptoms of renal irritation—albuminuria, with or without renal elements—frequently developed. The same is true of Asiatic cholera. It was long ago pointed out by Senator and others that intestinal obstruction, invagination, etc., often produces albumin, casts, and renal epithelium in the urine. It is, of course, necessary, to know that a previous kidney difficulty did not exist before drawing a strong inference from such an albuminuria. The colic which accompanies the obstipation has much to do with the production of albuminuria. By a daily examination of the urine in these cases it was possible to say on what days there were colicky pains and upon which days there were none.

At the session of May 6th LANG said that he treated lupus with hot air with good results. A tube from which the hot air comes is held at less than half an inch from the surface of the skin, which can support without much pain air of from 200° to 300° C. A yellowish-white eschar is at once produced, the irritation spreading laterally as well as into the depths of the tissue. When this comes away there forms a healthy cicatrix, or if some spots of lupus remain the treatment may be repeated. This method of treatment is especially recommended for lupus erythematosus, a form which is not amenable to the present modes of treatment.

FRANK spoke of the freedom from recurrence of malignant growths long after their removal, showing a patient who had come to him for prolapse of the anus eight years after Kraske's operation had been performed for carcinoma of the rectum. There was no sign of recurrence.

ALBERT said that even eight years are too few to give perfect security, for recently he saw recurrence in a similar case ten years after the operation.

WEINLECHNER had seen a recurrence of carcinoma of the tongue thirteen years after its removal. Such a long interval leads to the view that the "recurrence" has nothing to do with the original tumor, but that the individual is predisposed to the development of malignant growths.

The study of 104 cases of carcinoma, subjected to operation, convinced HOCHENEGG that the character of the operative effort had nothing to do with the question of recurrence. The latter was, in his opinion, simply a continuance of the unremoved portions of the growth.

SCHNITZLER extirpated a portion of a sarcoma of the sole of the foot, amputation being refused. The wound healed, and some time afterward there developed in the scar a small tumor, which the patient permitted him to remove, again refusing a more radical operation. This was microscopically diagnosed as round-celled sarcoma.

EWALD mentioned a case of carcinoma of the uterus, which was so extensive that a part of one ureter was removed, a nephrectomy following. It was supposed by all that the patient would die in a short time of continuation of the growth. She lived six years without sign of recurrence, and then died of embolism of the remaining kidney. In the scar tissues of the hysterectomy were found portions of the carcinomatous tumor, which had remained quiescent.

At the session of May 13th, SCHNITZLER narrated an instance in which a painless reducible femoral hernia became strangulated. Three hours later it was reduced by taxis, but from that time on, whether it was reduced or not, there was a great deal of pain, and frequent attacks of colic and tympanites. Operation showed a portion of the ileum about five inches in length to be so thickened that it was resected. Its lumen was fairly well preserved, however. The intestine above was much distended, and there was contraction at both places where the ring had pressed on the bowel, the lumen at these points being very small, and the mucous membrane destroyed. Other cases similar to this have been recorded, but in all of them the duration of the strangulation before reduction of the hernia has been much longer.

KRETZ compared the autopsies of patients who have died from diphtheria since the general use of serum with those of the preserous period. While in those days the majority of the deaths were due to the simple uncomplicated diphtheritic processes, in these days this class of autopsies has become rarer, while late deaths from paralysis of the heart and so-called postdiphtheritic tabes have become relatively and absolutely more frequent. The explanation of this is that many patients who without serum would have fallen victims to the early lesions, are saved by the serum from them, but succumb to the later lesions. That the heart failure is not due directly to the action of the serum is shown by the microscopical examination of the muscles of the heart. The changes therein are identically the same as those which occur in the hearts of patients who have received no serum. There are also no alterations in the kidneys which can be traced to the action of the serum.

A French Law.—One of the provisions of the French Code forbids a physician to inherit property left him by a deceased patient.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Forty-ninth Annual Meeting, Held at Denver, Col., June 7, 8, 9, and 10, 1898.

[Specially Reported for the MEDICAL NEWS.]

(Continued from page 830.)

GENERAL SESSION.

THIRD DAY—JUNE 9TH.

THE Association met at 11 A. M., with the Fourth Vice-President, DR. HAPPEL, in the chair.

The report of the Board of Trustees was read by DR. GARCELON of Maine. He said that the Association was to be congratulated on its growth and prosperity. The Board noted with pleasure that the leading medical colleges are lengthening their curriculum of instruction. Reference was made to the growth of the Journal from 1883, when the experiment was first tried of publishing a weekly, to the present time. The first issue of volume I. was circulated July 1, 1883, and 3500 copies of that date were printed, being largely in excess of the membership of the Association. At this time the membership, including both delegates and permanent members, did not exceed 1500. During the succeeding years the growth was slow, during 1887 there being an increase of but 161. Since then the membership has materially increased, as well as the general circulation of the Journal. The appearance and general make-up of the Journal are highly satisfactory. Viewed as a medical newspaper, it now undertakes to publish everything in current news that will interest the physician. A financial statement of the Journal for the fiscal year followed, ending December 31, 1897, showing a balance on hand of $14,092.85. To the report was appended an inventory of the Journal property. The balance in the treasury is so satisfactory that the Board had directed an additional $10,000 to be placed to the credit of the investment fund created by the Association in 1896 for the purpose of providing a permanent building for the home of the Journal. In accordance with the recommendation the Board has become an incorporated body and now has definite standing as a legal corporation. In conclusion the Board recommended that each member make a renewed effort to increase the membership, encourage subscriptions, and extend the good influence of the Association for the advancement of medical knowledge and the general welfare of the profession.

On motion the report was ordered printed and Dr. Garcelon was extended a vote of thanks for reading it.

DR. GIHON reported on behalf of the Rush Monument Fund that he had received nearly $12,000.

DR. U. O. B. WINGATE of Milwaukee read the report of the Special Committee on Department of Public Health. The bill, already familiar to the profession, was referred to and its salient points outlined. The report closed with the following resolutions:

Resolved, That the committee be continued, that the bill as now perfected and before Congress be approved, and that the Committee use its best endeavors to have it passed by Congress.

Resolved, That the members do all in their power to urge upon their Representatives the passage of the bill.

Resolved, That the Association appropriate the sum of $1000, or so much thereof as may be necessary, for the use of the Committee in the endeavor to have this measure passed.

On motion the report was referred to the Executive Committee with power to act.

DR. H. O. WALKER of Detroit read the report of the Committee on Nominations as follows: President, J. M. Matthews of Louisville; first vice-president, W. W. Keen of Philadelphia; second vice-president, J. W. Graham of Denver; third vice-president, H. A. West of Galveston; fourth vice-president, J. E. Minney of Topeka; treasurer, Henry P. Newman of Chicago; librarian, George W. Webster of Chicago; trustees, Alonzo Garcelon of Maine, T. J. Happel of Tennessee, I. N. Love of Missouri; to fill vacancy, H. L. E. Johnson of the District of Columbia. Members of Judicial Council: S. S. Bailey of Iowa, D. R. Brower of Illinois, H. D. Didima of New York, D. Mason of Washington, F. T. Rogers of Rhode Island, M. B. Ward of Missouri; to fill vacancy, W. S. Jones of New Jersey. General addresses: on medicine, J. C. Wilson of Pennsylvania; on surgery, Floyd W. McRae of Georgia; state medicine, D. R. Brower of Illinois. Place of meeting, Columbus, O., June 7, 8, 9, and 10, 1899; chairman, committee of arrangements, Starling Loving of Columbus; assistant secretary, E. W. Woodruff of Columbus. On motion the report was unanimously adopted.

The Executive Committee reported through its secretary, Dr. Bulkley, that under the existing laws of the Association it did not feel competent to recommend the adoption of the suggestions contained in the President's address.

Relative to the Rush Monument Fund, the Executive Committee endorsed the nomination of Dr. Henry D. Holton as treasurer, as recommended by Dr. Gihon in his report at a previous general session. This recommendation was adopted by the Association.

The Executive Committee had examined the treasurer's report and had found it correct and the books neatly kept.

The Executive Committee recommended the adoption of the resolution offered by Drs. Dudley S. Reynolds, W. W. Keen, George M. Gould, and William Bailey, and their action was ratified by the Association.

As to the Hare resolution, in relation to admitting the New York State and New York County Medical Societies, the Executive Committee reported that while it was fully in sympathy with and endorsed the idea proposed in the resolution, it felt that it involved a question which did not properly come within the province of the Executive Committee, and that the matter concerned the Association at large. After a spirited debate, participated in by Drs. Hare, Scott, Ferguson, Love, Munn, Jackson, Bishop, and Meyer, the Chair declared the matter out of order amid great laughter and cheering.

The Executive Committee favored and the Association adopted the button of Dr. Stone as the permanent button of the Association. As to the recommendation in the re-

port presented by Dr. Humiston, the Executive Committee did not recommend the appointment of such committee.

DR. JOHN B. MURPHY of Chicago then delivered the general address on surgery. He selected for his subject, "Surgery of the Lungs." He stated that an analysis of what had been accomplished in this special line of work was of great interest, the advancements having been made by individual and unsupported efforts. The profession at large had never entered into this field with the enthusiasm, persistency, and energy with which it had invaded other regions, as the peritoneum, the genito-urinary, and the osseous and nervous systems.

In considering operations upon the lung several questions arise: (1) Is the lung, situated in its bone-bound cavity, accessible to surgical manipulation? (2) What are the difficulties and dangers encountered in entering this bony cavity? (3) To what extent may this wall be removed and replaced and what latitude of manipulation is permitted within the chest? (4) What will be the effect of opening the pleura in pneumothorax in cases of adhesions, and without adhesions? (5) How can its dangers be avoided or lessened? (6) Should the pleura be closed or drained? (7) Can the lung be incised, excised, or defunctionalized? (8) In pneumotomy, what are the dangers and limitations? (*a*) Hemorrhage from opening the chest; (*b*) pneumothorax from opening the bronchi; (*c*) pleuritis of the same and opposite side; (*d*) traumatic pneumonia; (*e*) sepsis? (9) What are the pathologic conditions of the lung requiring excision in (*a*) hernia, (*b*) infected injuries, (*c*) abscesses, (*d*) bronchiectasis, (*e*) gangrene, (*f*) removal of foreign bodies, (*g*) tubercular cavities, (*h*) hydatids, (*i*) actinomycosis? In pneumotomy, the dangers and limitations may be further classified as immediate hemorrhage, pneumothorax, and dyspnea, and secondarily, as shock, dyspnea, hemorrhage, sepsis, pleuritis, and pneumonia on the opposite side.

He then dwelt upon the best method of treating the intrathoracic stump, and upon drainage and closure. He also expatiated upon the process of repair in the stump, and upon how the chest is filled after excision. He next described how the lung may be defunctionalized artificially and quiescence maintained by injections into the pleural cavity by resection of the ribs, which allows the chest-wall to collapse, and by thoracotomy with separation of pleural adhesions and compression of the lung. The technical difficulties of intrapleural injections are adhesions and consolidations, while its technical dangers are air embolism, subpleural emphysema, pulmonary emphysema, dyspnea, and sepsis.

If pathology indicates, and clinical experience justifies, resection of the ribs to allow collapse of the lung, the same conditions demand thoracotomy with separation of adhesions and compression of the lung.

DR. MURPHY was extended a vote of thanks for his interesting and instructive address, after which the Association adjourned.

FOURTH DAY—JUNE 10TH.

DR. HAPPEL in the Chair.

DR. WILLS of California offered an amendment to the Constitution to the effect that the president, vice-presidents, treasurer, librarian, secretary, assistant secretary, and chairman of committee of arrangements shall be nominated by a special committee consisting of one member from each State represented at the meeting, and they shall be elected annually by vote, and shall hold office until their successors are elected. (This amendment lies over one year.)

DR. HAPPEL offered the following: *Resolved*, That an exact time be fixed at future meetings of the Association by the committee of arrangements, when the different general Addresses shall be delivered, and that when that time arrives all business shall be laid aside till the addresses have been finished. (Lies over one year.)

DR. C. LESTER HALL offered a resolution to the effect that the permanent secretary shall furnish incoming secretaries of sections with a list of names of those attending the various sections each year. Adopted.

The Committee on Transportation for the next meeting consists of H. L. E. Johnson, I. N. Love, C. A. L. Reed, X. C. Scott, E. D. Ferguson, and Starling Loving.

DR. LOVE presented the following resolution: *Resolved*, That the permanent secretary be required to have the official stenographic report of the proceedings of the general sessions transcribed verbatim and ready for consideration and correction, if need be, each day before being adopted. Carried.

A resolution was offered, and carried, that the permanent secretary furnish a copy of the Constitution and By-Laws and Code of Ethics to the proper authorities who have in charge the preparation of the program, with instructions to print the same in the regular official program each year hereafter.

Amendments to the Constitution and By-Laws:

1. Offered by Dr. W. L. Wills: Art. IV. — Officers. Amended to read: "Each officer shall hold his appointment for one year, and until another is elected to succeed him." This was tabled.

2. Offered by Dr. H. B. Ellis: Art. IX. — Conditions for further representation: "Any State or local medical society, or other organized institution, whose rules, regulations, and code of ethics agree in principle with those of this Association may be entitled to representation on the advice or agreement of the Judicial Council." This amendment was also tabled.

3. That the name of the Section on Dental and Oral Surgery be changed to that of Section on Stomatology. Adopted.

4. Offered by DR. L. D. BULKLEY: That "All new business shall be introduced not later than the third day of the session." To this amendment there were added the words, "unless there be objection," after which it was adopted.

After the presentation and adoption of resolutions of thanks, the Association adjourned to meet in Columbus, Ohio, the first Tuesday in June, 1899.

The official registration of members was 1336.

SECTION ON SURGERY.

SECOND DAY—JUNE 8TH.

AFTERNOON SESSION.

THE USE OF MIXED TOXINS OF ERYSIPELAS AND BACILLUS PRODIGIOSUS IN THE TREATMENT OF INOPERABLE SARCOMA, WITH IMMEDIATE AND FINAL RESULTS BASED UPON A PERSONAL EXPERIENCE OF SIX YEARS,

was the subject of a paper by DR. WILLIAM B. COLEY of New York.

He reported having treated eighty-four cases with the toxins and had restricted their use to inoperable sarcoma. He described the methods of preparation of the toxin used, and stated that he frequently employed the filtered toxin in the case of children. Greater virulence, it was stated, was obtained by passing the toxins through rabbits, and the author always preferred to use the combined toxins of erysipelas and bacillus prodigiosus. It was claimed that although the results obtained have been asserted by some to be local, this really is not so, as the action is both systemic and local, but when possible the injections are given locally. The severity of the reaction depends largely upon the rapidity of absorption. Referring to the question of dosage, the speaker stated that he began with a minimum dose and slowly increased daily, the dose depending upon the virulence of the culture. If used subcutaneously, much larger doses may be given. In cases of speedy reaction nausea and vomiting occur, but it is not necessary to produce a chill with every injection. In commenting on the loss of weight during the treatment he stated that this was not true unless the dose was too large. As to the change in the tumor itself, macroscopically, it became less vascular and less glossy in appearance as well as smaller in size. Concerning the duration of treatment, one can soon tell whether or not any good is being accomplished by this method of treatment, and it should not be continued unless improvement begins within three weeks.

In closing the discussion which followed the reading of the paper, Dr. Coley said that the results obtained from the use of the toxins in carcinoma had not warranted their continuance, and in only one case of epithelioma of the mouth had good results followed. As to the possibilities of sarcoma and gummata being confounded, he thought that was only possible in round-celled sarcoma. In fifty per cent. of his cases of spindle-celled sarcoma which had been hopelessly inoperable the growth had practically disappeared under the influence of the toxins.

DR. W. W. KEEN of Philadelphia then read a paper on

THE ADVANTAGES OF A PERMANENT ARTIFICIAL ANUS, AND OF TOTAL CLOSURE OF THE SACRAL END OF THE RECTUM, IN OPERATIONS FOR CANCER OF THE RECTUM.

The author reported having operated on seven patients, of whom four recovered, three died, and two were well at the end of five and one-half years. Both of the latter were men, and are, at the present time, able to ride bicycles, and may be considered as cured, having passed the three-year limit. He laid great stress upon the danger of infection during and after these operations and stated that the operation preferred by himself in making an artificial anus is that instituted by Maydl. A great point in favor of the artificial anus in these cases is that the upper half of the tumor can be cleaned out from above and the lower half from below. One objection to the old operation is the necessity of wearing a napkin day and night in addition to the fact that there is often very considerable prolapse of the bowel.

DR. CHARLES A. POWERS of Denver showed three patients in lieu of reading a paper. The first was a child, who, at the age of three months developed a large coccygeal tumor which he believed to be a tubulo-dermoid.

The second subject was an excellent example of what the Murphy button can accomplish under very unfavorable circumstances. The patient had had appendicitis for three weeks, intestinal obstruction for four days, and a tumor the size of a football was present, so that his condition was very precarious. Upon making an incision a large amount of pus was liberated, and a drainage-tube was inserted. Within twenty-four hours he developed a fecal fistula at the site of the tube, and an enterectomy was performed shortly afterward, a Murphy button being inserted, which was passed on the thirtieth day, and the fistula subsequently closed. A third operation was performed later for the removal of the appendix.

The third case was one of a T-shaped fracture at the elbow-joint Dr. Powers stated that some surgeons claim that it is difficult to obtain good results if in these cases the arm is treated in the extended position, but he did not think this was true. He believed the best position is of slight abduction of the arm, a splint being applied at an angle of about 150 degrees, and at the end of a week bringing it up nearer to an angle and each week flexing it still further. He believed that as good results can be obtained from the flexed position as from the extended, and considered it much safer.

DR. H. A. HARE of Philadelphia read a paper, entitled

THE MEDICAL ASPECT OF APPENDICITIS.

In the author's opinion, all cases of appendicitis are not operable. He drew attention to typhoid fever as a complication of appendicitis, and to the frequent lack of typical symptoms of appendicitis, even when it is present. He concluded his paper by dividing the subject into three classes of cases: first, those that undoubtedly should be operated upon; second, those about which doubt exists; and, third, those in which the patient recovers from moderate attacks and have no more.

DR. H. D. NILES of Salt Lake City read a paper, entitled

THE TIME TO OPERATE IN APPENDICITIS.

The speaker argued strongly in favor of immediate operation in all cases, and gave it as his belief that if this were done the mortality would not exceed two per cent. He stated that the present death-rate in cases of first attack is one per cent., while in subsequent attacks it is twenty-five per cent.

DR. WILLIAM N. HARSHA of Chicago read a paper, entitled

THE EARLY TREATMENT AND INDICATIONS FOR OPERATION IN APPENDICITIS.

He referred to the best medical treatment in these cases by mentioning opium in the form of codein for the pain, and cathartics for the bowel. He believed that twenty-four hours is sufficient in which to decide whether surgical interference is necessary, and considered that the sooner the operation is performed the better in cases of the fulminating variety.

THIRD DAY—JUNE 9TH.

DR. A. H. LEVINGS of Milwaukee read a paper, entitled

THE COURSE AND TREATMENT OF INJURIES TO THE PERIPHERAL NERVES.

After referring at some length to a number of cases of injuries to nerves and to various methods of treatment, he referred to five important headings under which the matter should be considered: (1) the absolute necessity of asepsis; (2) the nerve should not be separated from its connective-tissue surroundings; (3) the approximation of the ends should be made without tension; (4) if an inch or more be lost, the gap should be bridged with some material having longitudinal strands; and (5) contrary to the common belief, absolute rest of the limb is not necessary.

DR. R. HARVEY REED of Rock Springs, Wyoming, read a paper, entitled

POST-OPERATIVE INSANITY.

He reported several cases occurring in his own practice and in the practice of others, and read a number of extracts from letters received from surgeons throughout the country on this subject. He stated that sometimes slight operations are followed by severe forms of insanity, and referred to a case of insanity which had been cured by an operation for an entirely different condition.

DR. HENRY O. MARCY of Boston read a paper, entitled

TENDON SUTURE; ITS PREPARATION AND USES.

He showed several different kinds of tendons, prepared in various ways, and pointed out the merits and demerits of each.

Extracts from the paper by DR. GEORGE W. CRILE of Cleveland, for which the author was awarded the Senn medal for 1898, entitled

EXPERIMENTAL RESEARCH INTO THE EFFECTS OF TEMPORARY CLOSING OF THE CAROTID ARTERIES; REPORT OF A CASE; EXHIBITION OF A NEW INSTRUMENT,

were read, but in the absence of the author there was no discussion.

DR. GEORGE W. JOHNSON of Dunning, Ill., read a paper, entitled

RADICAL CURE FOR HERNIA AND HYPERTROPHIED PROSTATE IN OLD MEN; REPORT OF CASES.

The author reported having operated on fifty-seven patients, in one of whom hernia resulted and was followed by death. It was stated that the lateral lobes of the prostate may be enlarged without giving rise to symptoms, but in most cases frequent and painful urination are prominent factors, as well as tenesmus and painful defecation. He believed that operative treatment should be faithfully tried in all cases.

DR. FERD. C. VALENTINE of New York read a paper, entitled

A CONTRIBUTION TO THE STUDY OF THE SYMPTOMS OF CHRONIC GONORRHEA.

He stated that the first sign of gonorrhea is an agglutination of the meatus, and that the disappearance of the discharge causing this condition does not prove the cure of the disease. The discharge in both acute and chronic cases varies very much, as do the color of the stains on linen. He commented on the fact that spermatorrhea may exist coincidentally with urethritis.

DR. BAYARD HOLMES of Chicago read a paper, entitled

ADRENAL TUMORS IN THE KIDNEY.

The doctor referred to the various results from injury and removal in part or in whole of the suprarenal capsule and to the relation of these bodies to the kidneys.

DR. HOWARD A. KELLY of Baltimore read a paper entitled

PNEUMATURIA.

In taking up this subject, Dr. Kelly divided it into four classes: (1) that in which the air is mechanically introduced from without; (2) in which the gas develops in the urinary tract; (3) in which the gas reaches the bladder from the surrounding area; and (4) in which the gas originates in the kidneys and ureters. He reported a number of cases observed by himself and commented on the possibility of the appendix sometimes being the cause of pneumaturia.

DR. JAMES M. ANDERS of Philadelphia read a paper, entitled

ETHER PNEUMONIA.

After referring at great length to the causes and symptoms of this condition it was stated that various nose and throat troubles, such as rhinitis and bronchitis, are important predisposing factors to ether pneumonia. He stated that most cases occur during cold and changeable weather, and he believed that the amount of ether used and the method of administering has much to do with causing the occurrence of this condition.

DR. H. M. SHERMAN of San Francisco read a paper, entitled

TREATMENT OF CONGENITAL DISLOCATION OF THE HIP.

In referring to the cause for the stiffness that sometimes appears late in these cases, the author stated that cicatricial contraction has much to do with the condition. He described in detail his method of treatment and quoted a number of cases in which he had obtained excellent results.

The officers appointed for the ensuing year were as follows: Chairman, W. J. Mayo of Rochester, Minn.; Sec-

retary, M. L. Harris of Chicago; Committee on Senn Medal, A. D. Bevan of Chicago, Chas. A. Powers of Denver, Wm. B. Coley of New York.

SECTION ON NEUROLOGY AND MEDICAL JURISPRUDENCE.

THIRD DAY—JUNE 9TH.

The first paper of the morning session was by DR. FRANK P. NORBURY of Jacksonville, Ill., entitled

MELANCHOLIA.

His conclusions were, briefly stated, as follows: The mind has a physical basis: the brain is the organ of the mind, its activity is dependent upon nutrition; when badly nourished melancholia results. Melancholia is therefore a nutritive disorder. In melancholia generally bodily nutrition is as much a part of the disease as are the mental symptoms.

DR. MEYER of New York thought from observation of a large number of cases of melancholia, so-called, that one deals with quite a number of different disease processes.

DR. LICHTY of Union Springs, New York, said his own experiments along the line of Haig's investigations as to faults in nutrition had been rather disappointing.

DR. PUNTON of Kansas City thought there should be detention hospitals, midway between the home and the insane asylum for the treatment of melancholics.

DR. RIGGS of St. Paul, Minn., thought the treatment received in asylums by those suffering from melancholia, in the majority of cases, is the best possible for that condition.

DR. HERDMAN of Ann Arbor, Mich., related two cases of melancholia in women which were entirely relieved by removing the disturbing or exciting causes, namely tumor of the uterus, and retroflexion of the uterus, respectively. He thought it extremely important to know what these reflex disorders produce in the way of changed metabolic disturbance.

DR. TOMLINSON of Missouri protested against calling every depressed individual a melancholiac. The paper was also discussed by Dr. Woodson, Dr. Searcy of Alabama, and Dr. Hughes of St. Louis. Dr. Hughes said that the prognosis in melancholia, when treated properly at an asylum, is very favorable.

DR. SHERMAN G. BONNEY of Denver read a paper on

FUNCTIONAL NERVOUS DISTURBANCES IN PULMONARY INVALIDS,

relating his experiences in a large number of cases of phthisis.

The Nominating Committee made its report, which was duly accepted. The officers for the next year are as follows: Chairman, Frederick Peterson of New York; secretary, Hugh T. Patrick of Chicago. Executive Committee: T. D. Crothers of Hartford, W. J. Herdman of Ann Arbor, Mich., Charles H. Hughes of St. Louis, Mo.

DR. SAMUEL BELL of Newberry, Mich., read a paper on

SOME RESULTS OF THE ADMINISTRATION OF THYROID EXTRACT ON THE RED AND WHITE CORPUSCLES AND HEMOGLOBIN IN CASES OF ANEMIA ASSOCIATED WITH MELANCHOLIA.

At the Upper Peninsula Hospital for the Insane (Michigan) nine patients were under treatment in the first series, seven females and two males, all suffering from some form of mental depression. Blood examinations were carefully made. In one of the cases the red corpuscles were increased 728,400, leucocytes 1330, and hemoglobin 7 per cent. Nine patients received thyroid medication, and were under close medical supervision; in five cases there was a marked change for the better; the other four were not favorably influenced, so far as could be observed. Three of the five who improved began to increase in weight during treatment, and two of them did not until after treatment was relinquished. The psychologic effect was observed almost from the beginning of treatment in those who were permanently improved.

The next feature of the afternoon's program was a

SYMPOSIUM ON BRAIN TUMOR,

participated in by the following: Dr. Charles H. Hughes of St. Louis, who spoke of the "Symptomatology;" Dr. Frederick Peterson of New York, on "Localization;" Dr. Edward Jackson of Philadelphia, on "Ocular Symptoms;" Dr. Philip Coombs Knapp of Boston, on "Treatment from the Neurologic Aspect;" and Dr. W. W. Keen of Philadelphia. on "Treatment from the Surgical Aspect."

DR. HUGHES spoke of the symptomatology of tumors of the brain, and the necessity of understanding, not only the symptomatic expressions, but also the secondary states of the brain which their presence induces. Conditions of the intracerebral circulation, excited by or preceding the development of a neoplasm, glioma, or other growth within the brain by a morbid cause projecting within it from the brain's enveloping membranes or bony covering, cause a symptomatology (cephalalgia, neuroretinitis often, and sometimes glaucoma) which may exist independently of any form of intercerebral or intracranial morbid growth. Hysteria complicates, even as it is sometimes complicated with, cerebral tumor. Altered cerebral circulatory states, especially of vasomotor cause independent of intracranial growths, are not continuous as tumors are. Chief among the persisting signs are the eye fundus and pupillary signs, the paralyses of cerebral sources, mono- deutoplegias, etc., mono- or deutospasm, tremors, the epilepsies, the vertigos, motor- and special-sense paralyses, the incoordinations, anesthesias and pains due to regional or general cerebral irritation or pressure, and the degenerations due to intracranial pressure. Here we are confronted in the symptomatology with the possibilities and consequences of cerebral sclerosis, atheromatous, inflammatory or specific vascular changes, emboli, thrombi or thrombotic inflammation of vessels, apoplectic sequelæ, abscesses, interstitial nephritis, uremic, alcoholic, or other toxipathies, involving the brain, its vessels, texture or coverings, and serous ventricular or subarachnoid effusions. Insanity is often a marked symptom of tumors.

DR. PETERSON referred to the localization of brain tumors, and presented several charts, one showing the localization of functions in the cortex, another to illustrate the localization of speech functions, showing the centers of language and the result of the lesions of the same.

DR. EDWARD JACKSON mentioned optic neuritis as the most striking and significant symptom, occurring in eighty or ninety per cent. of all cases. It cannot, however, be regarded as pathognomonic, and it is of little value to indicate the location of the tumor. The typical optic neuritis of brain tumor is characterized by great swelling, sometimes 10 or 12 D. (3 millimeters), abruptly limited, at no great distance from the margin of the disk; with arteries narrowed, veins dilated, and very tortuous, and small vessels much enlarged but not very numerous because scattered through the swollen tissue; small flame-shaped hemorrhages upon or near the papilla; the other portions of the fundus, except for the alteration in the vessels, being normal, or presenting changes which are in most cases slight as compared with those at the disk. In contrast with the above, swelling and discoloration of the disk, occurring as an anomaly, are never of very high degree. Dr. Jackson also referred to optic atrophy, changes in the pupil with impairment of accommodation, paresis of the extra-ocular muscles, nystagmus, impairment of central vision and limitation of the field of vision, and impairment of color perception.

DR. KNAPP said that out of 405 cases collected by him in 34 the growth was found but could not be removed; in 92 the growth was not found at the point of operation, and in 224 the growth was found, but in 34 of these cases the growth was of such a nature that it could not be wholly removed; 55, or 14 per cent., were palliative operations, some of which were perhaps real cases in which there was a mistaken diagnosis. Dr. Knapp was not very sanguine as to the results of operation in cases of tumor, but he dwelt upon the advisability of operative procedure in gummata and tubercular growths. The greatest danger is in sarcomata and glycomata, the likelihood of recurrence being especially marked.

DR. W. W. KEEN referred to the difficulty of localization, and urged that every one of these cases be subjected to faradism during the operation before the tumor or the brain is touched. He deplored the antivivisectionist measures, which, if persisted in, would seriously hamper brain surgery and prevent its advance. As to the technic of the operation, Dr. Keen advocated a very large opening, giving a better opportunity to ascertain the location of the tumor.

DR. T. J. ESKRIDGE of Denver reported

A CASE OF INTRADURAL TUMOR OF THE SPINE; REMOVAL; COMPLETE RECOVERY,

and exhibited the patient.

DR. DANIEL R. BROWER of Chicago contributed a paper on

ACUTE MENINGITIS; OBSERVATIONS ON DIFFERENTIAL DIAGNOSIS AND TREATMENT.

He laid emphasis on the Skeer sign, which, when present, will enable a diagnosis of tubercular meningitis to be made very early. It is due to the deposition of tubercle around the pupillary margin of the iris, showing itself first as a distinct wreath of white clouds about a millimeter from the margin. This sign occurs before any change has taken place in the size of the pupillary orifice. After three or four days these minute cloud-like masses disappear, and a yellowish-brown circle takes their place, becoming more and more attenuated, as the pupil dilates. These secondary changes are doubtless due to degeneration of blood-vessels and tissues from tubercular deposits. Unfortunately this sign is frequently absent, but when present Dr. Brower regards it as pathognomonic of tubercular meningitis. Dr. Brower advocated the iodoform treatment by inunction. He prefers a ten-per-cent. ointment of iodoform and lanolin, applied daily to the shaven scalp. Absorption takes place promptly, and iodin may sometimes be discovered in the urine and saliva one hour after the inunction. Out of forty-five cases treated in this way there were thirty-two recoveries.

DR. C. EUGENE RIGGS of St. Paul presented

A CASE OF REYNAUD'S DISEASE, WITH AUTOPSY,

exhibiting notes of sections of the cord.

SECTION ON DISEASES OF CHILDREN.

SECOND DAY—JUNE 8TH.

A paper, entitled

WHAT INFLUENCE DO STIMULANTS AND NARCOTICS EXERT ON THE DEVELOPMENT OF THE CHILD,

was read by DR. E. STUVER of Rawlings, Wyoming. After referring to the functional disorders produced by tobacco, the essayist spoke of the effects upon the moral nature. Much of the pallor, anemia, malnutrition, and evidences of retarded growth and development, especially among the poorer classes, is largely due to the tobacco-poisoned atmosphere in which children are compelled to breathe. The pathologic and moral effect of alcohol on the human organism were also considered at length.

In the discussion, DR. SLAGLE of Minneapolis gave an instance of an infant made so ill by tobacco fumes that a fatal prognosis was made.

DR. LAUTENBACH of Philadelphia had seen a victim of tobacco blindness only thirteen years of age. Tobacco probably never does good and frequently does harm, probably greater harm than alcohol. It is more difficult to persuade patients to stop the use of tobacco than alcohol.

"The Treatment of Tuberculosis in Children in New York City; Remarks Based on Ten-Years' Experience," was the title of a paper read by DR. LOUIS FISCHER of New York. This was followed by papers on "Tubercular Peritonitis," by DR. F. F. LAWRENCE of Columbus, Ohio; "Immediate and Forcible Straightening of Spinal Curvatures," by DR. RIDLON of Chicago; and "Auto-Infection *versus* Typhoid Fever as Seen in Young Children," by DR. HOLLOPETER of Philadelphia.

Officers elected for the coming year were: President, Dr. Henry E. Tuley of Louisville; secretary, Dr. J. L. Booker of St. Louis.

A paper, entitled

IS THE USE OF THE TERM "TYPHOID PNEUMONIA" JUSTIFIABLE?

was read by DR. HENRY E. TULEY of Louisville.

In the case reported many symptoms pointed toward typhoid fever, yet no evidence was found post-mortem except slight enlargement of the mesenteric glands. On the twelfth day there were no signs of consolidation of the lungs. Autopsy revealed the lungs to be almost completely consolidated. Bacteriologic examination of the lungs revealed the presence only of diplococcus pneumoniæ. In such cases the essayist believed the term "typhoid pneumonia" justifiable.

Papers on "Artificial Feeding in Digestive Disturbances of Infants," by DR. J. G. M. CARTER of Waukegan, Ill., was read by Dr. Charles D. Spivak of Denver; "Formative Nutrition," by DR. H. W. SCAIFE of Chicago; "The Debility of Adolescence," by DR. LOUIS FAUGERES BISHOP of New York; and "Milk-Mixtures as Food for Infants," by DR. EDWIN ROSENTHAL of Philadelphia.

THIRD DAY—JUNE 9TH.

The first paper read was on "The Serum-Treatment of Diphtheria as Viewed by the General Practitioner During the Last Year," by DR. ALEXANDER MCALLISTER of Camden, N. J.; and was followed by "Data Derived from One Hundred Cases of Laryngeal Diphtheria, Including Fifty Intubations," by DR. ROSA ENGELMAN of Chicago.

THE PRECORDIAL AREA IN CHILDREN; A PRACTICAL DEMONSTRATION

wat the title of a paper by DR. HERBERT B. WHITNEY of Denver.

To the essayist there was nothing in physical diagnosis more definite and more certainly ascertainable than the normal area of precordial dulness. At the age of five years the precordial area is not perceptibly enlarged but corresponds practically to that of the adult. From the age of eight years up to and considerably beyond the age of puberty the normal precordia differs materially from that which is found in earlier life. Its right border now extends a half inch or even more beyond the right sternal margin; while the upper border is in the second interspace, and toward the left the precordia extends one-fourth to one-half inch beyond the mammillary line. During the fifth, sixth, and seventh years the conditions are inconstant. The enlarged precordia of childhood may be found even in the fifth year, but this is decidedly the exception. In the sixth year it is much more frequent; in the seventh it occurs in the majority of cases, while in the eighth year, as stated, it becomes constant. The percussion should be made with the finger, the stroke being light or of only moderate force. In percussing the right heart, the essayist laid considerable stress upon percussing along the sternum, marking the difference obtained in percussing the upper and lower part. The demonstration was made upon a number of children of various ages.

The paper was discussed by Dr. J. N. Hall of Denver, Dr. John H. Musser of Philadelphia, and Drs. Babcock, Cotton, Engelman, and Whitney.

OBSERVATIONS IN DIPHTHERIA

was the title of a paper by DR. H. D. JEROWITZ of Kansas City, Mo. The essayist observed that the majority of cases of diphtheria are mild, and affect only the tonsils and pharynx. The exudation lasts from one to two weeks. To this there are exceptions. Removal of the membranes is useless, as by denuding the surface infection is promoted, and, in addition, the membrane soon reappears, and remains longer than if it had not been meddled with. The involvement of the larynx is not always sudden and comes as a new attack, and not by extension of the diphtheritic process. The larynx becomes involved in about four per cent. of cases. Every case complicated by uremia in his experience had post-diphtheritic paralysis. Laryngeal involvement is to be most dreaded between the ages of three and five. Intubation and tracheotomy will become less and less necessary as the value of antitoxin is recognized.

"A Report of Thirty-eight Consecutive Intubations for Diphtheritic Croup, with Thirty-six Recoveries, all Treated with Antitoxin," was read by DR. F. E. WAXHAM of Denver; "Indications for Intubation," by DR. H. M. MCCLANAHAN of Omaha; "Disturbed Lactation; Some Causes and Effects," by DR. A. C. COTTON of Chicago, and "Dentition," by DR. JOSEPH CLEMENTS of Kansas City, Mo.

SECTION ON MATERIA MEDICA, PHARMACY, AND THERAPEUTICS.

SECOND DAY—JUNE 8TH.

DR. H. A. MOODY of Mobile read a paper on

POTASSIUM IODID IN CEREBROSPINAL MENINGITIS.

He said he unhesitatingly recommends the free use of potassium iodid in this disease. It can be administered by enema or inunction, so that the vomiting so often present in this malady is no obstacle to the use of the remedy. He passed through two epidemics, employing the ordinary remedies in the first, and in the second potassium iodid with other remedies, the percentage of mortality being greatly reduced.

DR. W. B. HILL of Milwaukee read a paper on

ANTISTREPTOCOCCIC SERUM.

He said the time is not far distant when other antitoxins will stand shoulder to shoulder with that of diphtheria. In the treatment of erysipelas by antistreptococcic serum the percentage of mortality is greatly diminished. In a case of facial erysipelas in a lady aged seventy-one years, with a temperature 104° F., pulse 146, antistreptococcic serum, 10 c.c., was injected at 2 P.M., and repeated later. The temperature became normal within a few hours, and tenderness disappeared, followed by prompt recovery. Any disease caused by streptococcic infection is benefited if not cured by the serum.

DR. R. G. ECCLES of Brooklyn read a paper discussing

THE PONS ASINORUM OF THERAPEUTICS,

in which he asserted that any therapeutic law which fails to come down to the bedrock of cause and effect is a mere

hallucination. All effective therapeutic measures are preventive ones. Our present failures are due to defective diagnosis. We cannot overcome this defect until we have a new nomenclature of disease. There is no such thing as a distinct disease, disease being only the resulting effects of a multitude of causes actively resisted by the body. A cure occurs when we suspend the action of the damaging force. The human body does its own repairing of the damage; we can only remove the causes. Prophylaxis is the soul of cure. Every disease of the body can occupy any part of the body. Instead of calling the disease pneumonia let us call it pneumococcus pneumonia, streptococcus pneumonia, or some bacillus pneumonia. To say simple pneumonia is misleading.

DR. T. D. CROTHERS of Hartford presented a paper, entitled

GOLD-CURES IN INEBRIETY.

He said the empirical preparations called gold-cures are found upon analysis to contain no gold whatever. Gold is non-assimilable and its modern use is confined to quacks who trade on the name. The modern craze for gold as a remedy is simply a repetition of charlatans, schemers of past centuries who sought to meet and supply the demand for elixirs of life. The value of the gold-cures depends upon credulity. A yellow mixture of some vegetable extracts injected in the arm and followed by general relaxation and diaphoresis has created a profound impression and it is believed that the hidden virtues of the drug will revolutionize pharmacy in the future. Injections of gold tried by the speaker have not been noticeable for any effects on the desire for spirits. By impressing the mind of the patient with a profound conviction of the value of the drug, and detailing the expected results which would follow, and using colored water, the exact effects would appear. Inebriety is more than alcoholism; it includes disorders of which the desire for spirits is only a symptom. The real trouble is some central disease of the brain so complex and obscure that no drug or therapeutic agent can reach it specifically. Experience indicates that it is extremely doubtful if any remedy exists for this obscure neurosis of the brain. The degeneration which precedes and follows the use of alcohol consists of organic changes of cell and nerve-tissue, and restoration is problematic and depends on causes and conditions largely unknown.

REVIEWS.

ORTHOPEDIC SURGERY. By JAMES E. MOORE, M.D., Professor of Orthopedia and of Clinical Surgery in the University of Minnesota, etc.; 354 pages; 177 illustrations. Philadelphia: W. B. Saunders, 1898.

IN the preface the writer states that the book is the work of a general surgeon who has taught orthopedic surgery for a decade. He has endeavored to point out the desirable middle ground between too much and too little operating, and has made a studied effort to reduce the size of the book by eliminating all that is not of practical value. The illustrations of the phases of disease and deformity are, as a rule, excellent. As much cannot be said for many of those indicating treatment. Even the plaster jackets, as applied by the author, are open to criticism, and it is hardly fair to assert that a Washburn back brace, figured with its pelvic band about the waist of the patient, "is practically identical with that of Taylor." A professor of "Orthopedia" ought to be more familiar with Andry's book than to assert that the inventor of the term limited it to the straightening of crooked children. A plaster cast is not identical with a plaster bandage, and the composition of an "A. S. & B. pill" may not be known to all students. The quotations are few and there is little excuse for the persistent misspelling of a name as well-known as that of Lorenz. In spite of its shortcomings, however, the book is to be commended as a clear, commonplace presentation of common-sense principles applied to the treatment of deformity.

A TEXT-BOOK OF SPECIAL PATHOLOGICAL ANATOMY. By ERNST ZIEGLER, Professor of Pathology in the University of Freiburg. Translated and Edited from the Eighth German Edition by DONALD MACALISTER, M.A., M.D., Linacre Lecturer of Physic and Tutor of St. John's College, Cambridge, and HENRY W. CATTELL, M.A., M.D., Demonstrator of Morbid Anatomy in the University of Pennsylvania. Sections ix–xv. New York: The Macmillan Company, 1897.

NO work on pathology has achieved greater success than Ziegler's, and the idea of presenting the last German edition to English readers deserves the warmest commendation.

The volume before us completes a work, which for attractive style and accuracy of statement, must always appeal to every student. A careful comparison, however, with the text of the seventh edition, which appeared in 1892, shows that a large part of the work is unchanged, though here and there a careful revision is apparent, and several chapters have been entirely rewritten, notably the sections on the causation of disease, on the induction of immunity by artificial means, on predisposition, and on inflammation, all of which, however, appear in an earlier volume.

In Sections ix–xv, the special changes in the diseases of the alimentary tract, the liver and pancreas, the respiratory system, the urinary organs, the genital system, the eye and ear are stated, though here the changes and additions are somewhat less conspicuous than those just mentioned, and for obvious reasons. The work is too well known to demand a consideration of each subject at our hands, and it must suffice to say that we know of no book on pathology which presents all the advances in our knowledge of disease in a more scientific or capable manner. As in the original German edition, an extended bibliographical list follows each section, giving the more important references to recent contributions. The illustrations are copious and excellent, being the same as in the original edition, and the typography leaves nothing to be desired. The publishers and editors are to be congratulated on the completion of a superb work.

OUTLINES OF RURAL HYGIENE; FOR PHYSICIANS, STUDENTS, AND SANITARIANS. By HARVEY B. BASHMORE, M.D. Philadelphia: F. A. Davis & Co., 1897.

AS the author states in his preface, "Much of the substance of the work has appeared from time to time in various medical journals;" nevertheless, this collection of essays on water-supply, waste-disposal, the soil, habitations, and disposal of the dead, should be carefully perused by both the profession as well as the laity, for there are therein contained many important facts which might promote health and sanitation of cities as well as of rural districts. The author has presented his subjects in a most interesting manner and should be thanked for the clearness and conciseness which he has combined in this little work.

DIE HAUPTSACHEN DER CHEMIE FUR DAS BEDURFNISSDES MEDICINERS. By DR. ERICH HARNACK, Hamburg. Leopold Voss, 1897.

THIS little book embodies in a concise manner all the most salient points in organic and inorganic chemistry, with short references to analytical methods employed in the various separations useful to the medical student. Its statements of chemical theory are both lucid and to the point, embodying all that is necessary for a complete comprehension of the matter therein contained. It might be recommended as a short guide on the subject, were it not that an alphabetical index to the subject-matter is lacking, which makes it somewhat difficult of access.

CHEMISTRY AND PHYSICS. A Manual for Students and Practitioners. By JOSEPH STRUTHERS, Ph. B., D. W. WARD, Ph. B., and CHARLES H. WILLMARTH, M.S. Philadelphia and New York: Lea Bros. & Co., 1898.

ONE of the series of "The Students' Quiz Series" with the above title has reached us, and, as usual in works of this type, we find that it answers its purpose admirably. The book being arranged in the question-and-answer method, it can be recommended as a guide to students preparing for examinations as well as a handy reference-book. Illustrations and a well-arranged index add to the value of the work.

A TEXT-BOOK OF THE DISEASES OF WOMEN. By HENRY J. GARRIGUES, A.M., M.D., Professor of Gynecology and Obstetrics in the New York School of Clinical Medicine, Gynecologist to the St. Mark's Hospital, etc. Illustrated. Second edition. Philadelphia: W. B. Saunders, 1897.

THE author of this well-known volume is to be felicitated upon the early demand of a second edition of his work. Such changes as he has made in this edition greatly enhance the value of the book. Many of the illustrations have been replaced by new ones and it may be said that up to the present time few books on gynecology so well and artistically illustrated have appeared in the United States. Especially of note are the illustrations of the anatomy of the female generative and pelvic organs and the text accompanying them is lucid and well adapted to the student's needs. We note other changes in the text, especially the equalization of vaginal and abdominal sections, the insistence upon aseptic surgery and a very good chapter on intestinal surgery included in the appendix.

It is not surprising to learn that Dr. Garrigues' book is used as a text-book in many of the colleges of the country. It is not only a good reference-book for the practitioner, but its wholesome advice, its clear reasoning, its simple statements, stripped of all unnecessary verbiage, its modern classification and methods, and its excellent illustrations render it an especially safe work to place in the student's hand.

THERAPEUTIC HINTS.

For Constipation.—When due to inactivity of the colon and diminished secretion of bile the following pill is of service:

℞ Ext. aloes, Quiniæ sulphat. } aa . . . gr. xxiv
M. Ft. pil. No. XXXII. Sig. One pill at night.

Treatment of Delirium Tremens by Sulphate of Atropin.—TONVIME has successfully treated a number of patients by means of hypodermic injections of this drug. In almost all cases a dose of $\frac{1}{60}$ of a grain produced a deep and quiet sleep.

For Scleroderma.—In this disease PHILIPPSOHN has obtained good results from the administration of salol, in doses of from 8 to 15 grains, repeated several times a day. The skin became more supple and in some cases even regained its normal condition.

Laxative for Infants.—

℞ Syr. mannæ . . . . . ʒ vi
Syr. rhei aromat. . . . . ʒ iii.
M. Sig. One-half to one teaspoonful.

Laxative for a Child.—

℞ Mannæ . . . . . ʒ iii
Magnesii carb., Sulph. loti } aa . . . . ʒ vi
Mellis . . . . . ℥ iii.
M. Sig. One-half to one teaspoonful.

For Goiter.—Frey recommends parenchymatous injections of the following solution:

℞ Iodoformi . . . . . grs. xv
Ether . . . . . *m.* lxxv
Ol. amygdal. dulc. . . . ʒ iiss.
M. Sig. Twenty to forty minims for injection into the parenchyma of the gland.

Tincture of Myrrh in Diphtheria.—Miloslawsky recommends painting the throat five or six times a day with undiluted tincture of myrrh, and the use of a one-per-cent. solution as a gargle. He also prescribes internally as follows:

℞ Tinct. myrrhæ . . . . . *m.* xl
Glycerini . . . . . *m.* lxxx
Aquæ . . . . . ℥ iv.
M. Sig. One to four teaspoonfuls every two hours, according to age of patient.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIII. NEW YORK, SATURDAY, JULY 9, 1898. NO. 2.

ORIGINAL ARTICLES.

THE TUBERCULIN TEST IN CERVICAL ADENITIS.[1]

BY EDWARD O. OTIS, M.D.,
OF BOSTON, MASS.

IT has been generally considered, I think, that a large number of cases of cervical adenitis are tuberculous, particularly if they are of slow growth and long continuance. The direct proof of this, however, as Volland[2] says, is very difficult to obtain, and I am not aware of any series of exact investigations undertaken to determine the proportion of tuberculous cases, or any decisive method of diagnosis in individual instances of the affection under consideration, other than the laborious one of making a microscopic examination of the contents and walls of the glands, or possibly by animal experimentation. In this latter method Bollinger[3] found that there must be a certain number of tubercle bacilli in the material injected to produce results, so that this test may fail. Volland,[4] in a series of observations made in Davos and its vicinity upon school children and others, found that among 2506 persons examined, enlarged cervical glands were present between the ages of 7 and 9 years, in 96 per cent.; between 10 and 12 years, in 91.6 per cent.; between 13 and 15 years, in 84 per cent.; between 16 and 18 years, in 69.7 per cent., and between 19 and 24 years, in 68.3 per cent. He comes to the conclusion from these observations (it is difficult to understand upon what definite grounds) that 68 per cent. of enlarged cervical glands are tuberculous. In persons known to be tuberculous in whom hard glands in the neck exist, Volland considers these tuberculous also and states that they will be found to contain tubercle bacilli or spores. In 108 phthisical patients he found that in 101 enlarged cervical glands were present. Cornet found in a Catholic sisterhood that of those sisters dying of tuberculosis, 63 per cent. had enlarged cervical glands which he considered tuberculous. When enlarged glands occur in childhood and persist in later life Volland thinks that when pulmonary tuberculosis develops in such cases the infection is conveyed from the glands to the lungs, and that it is very unlikely that the gland tuberculosis is secondary to that in the lungs. If this is true the importance of determining the nature of cervical glands can hardly be overestimated, for the treatment is both urgent and imperative.

It occurred to me that the tuberculin test was available for this purpose, being both easy and rapid in its application. I therefore determined to use it in every case of enlarged glands of the neck as such occurred in dispensary practice. No selection was made, but every case was tested, no matter whether the enlarged glands had existed a long or short period, or whether local irritation existed, such as a decayed tooth, the irritation from pediculi capitis, etc., which seemed the probable cause.

The tuberculin was obtained from the Massachusetts General Hospital in the form of a one-per-cent. solution of Koch's original tuberculin. The usual aseptic precautions were observed in making the injections: the needle was boiled, the syringe cleansed with ninety-five-per-cent. alcohol, and the site of injection scrubbed with soap and water and a bichlorid of mercury solution. The injection was usually given in the muscles of the upper arm, and there always resulted local induration, redness, and tenderness, disappearing within a few days. In no case did abscess result. Probably an injection into the muscles of the back would have caused less discomfort, but in an out-patient clinic the arm was more available. With ambulatory patients it was impossible to make frequent observations of temperature, although it was generally taken at the time of the injection and from six to twelve hours later. The statement of the patient as to his sensations was principally relied upon as to whether or not a reaction had occurred, and experience convinced us that this was safe evidence; in other words, dependence was placed upon the constitutional disturbance. If from six to twenty-four hours after the injection there occurred weakness, sensations of heat and cold, general malaise, nausea, anorexia, severe headache, pain in the back and limbs, a feeling, as many expressed it, as if they had the "grippe," and these symptoms were sharply defined both in their beginning and ending, a reaction was considered to have occurred. The group of symptoms described by the reaction cases was quite constant and so clearly expressed from a vivid realization of their experience that there seemed but little

[1] Read before the Section on Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, Boston, April 20, 1898.

[2] *Zeitschrift für Klinische Medicin*, 23, 1893.

[3] "Verhandlungen der Deutschen Naturforscher und Aerzte in Heidelberg," 1889; *Abth. Pathol. Anatomie*, s. 328.

[4] *Loc. cit.*

possibility of a mistake. The cases were all practically afebrile at the time of the injections. No evil results followed in any case further than the temporary reaction disturbance and the partially disabled arm for a day or two. Not a few expressed themselves as feeling improved, probably simply the contrast to the recent experience of the reaction. The glandular condition was not affected. In only one case could the reaction be said to have been excessive, and in this, after a dose of five milligrams, there was high temperature, a rapid and weak pulse, and great prostration. These symptoms, however, were but temporary. The reaction generally occurred from eight to fourteen hours after the injection and continued from twelve to thirty-six hours.

From 1 to 5 milligrams seemed to be the most satisfactory dose, and so far as our experience permitted a conclusion, was as efficient as 10 or more milligrams. It will be seen from the tabulated cases (Table I.) that out of 29, there were 18 positive reactions and 2 doubtful ones, from 62 to 69 per cent. Of the 11 cases in which reaction did not occur, in 6 the enlarged glands had only existed from 1 to 3 weeks, rather indicating that their origin was from some local irritation. The majority of the reactions occurred in cases in which the enlarged glands had existed six months or more, and this accords with the general opinion that tuberculous cervical glands are of slow growth and long duration. If, then, the tuberculin test is to be relied upon, our experience would indicate that at least 62 per cent. and probably a larger proportion of enlarged glands of the neck are tuberculous, but, of course, it requires a larger number of tests to verify this conclusion. It is interesting to note that in these 29 cases, 22 were in females; and in 17 instances the diseased glands were on the left side of the neck. These tests, so far as they go, corroborate the conclusions of others who have used tuberculin for diagnostic purposes, *viz.*, that there is no appreciable danger when the diagnostic agent is employed in moderate doses, and when there is doubt, as there always is, in a case of cervical adenitis, this test would appear to offer an easy method of settling the question as to the tuberculous or non-tuberculous nature of the glands. This settled, the question of treatment becomes more interesting and definite. Of course, I recognize the objection which will be raised: that the reaction may be caused by a tuberculous focus elsewhere, but I think it is fair to presume that it more likely to reside in the enlarged glands, other evidence failing to suggest its presence elsewhere.

Obtaining the reaction in a suspected case of cervical adenitis and considering that the diagnosis of tuberculosis is thereby established, the treatment indicated would seem to be twofold, *viz.*, general and local. The former should consist in fresh air, sunlight, abundant alimentation, good hygiene, and, in

TABLE I.—CERVICAL ADENITIS.

No.	Condition.	Duration.	Sex.	Age.	Dose in mg.	Result.
1.	Enlarged glands under right ear.	2 mos.	M.	18	1, 3, 10	No reaction.
2.			M.	6	1, 2	" "
3.	Suppurating gland in left neck.	1 mo. +	F.	10	1, 2	Reaction after 2 mg.
4.	Cervical abscess in left neck.		M.	3 mos.	1-10, 1-5	No reaction.
5.	Indurated mass under sternomastoid running up into region of the parotid. Has decayed teeth.	1 wk.	F.	40	2, 5, 10	Reaction after 10 mg. Swelling of joints of hand and feet persisting.
6.	Chronic suppurating gland in left neck.	2 yrs.	F.	23	5	Reaction.
7.	Enlarged submaxillary gland on right neck.	3-4 yrs.	F.	18	4	"
8.	Glands on right neck, one suppurating 5 months.	2 yrs.	F.	11	2	"
9.	Small glands both sides of neck, in occipital region.	3 wks.	F.		3, 5	No reaction.
10.	Mass of 6-7 glands extending from the left mastoid downward along the muscle.	10 mos.	F.	20	5	Reaction.
11.	Two glands in left neck below jaw.	3 wks.	F.	23	5, 10	Reaction after 10 mg.
12.	Two glands in left neck.	2 wks.	F.	9	3	No reaction.
13.	Suppurating glands in left neck; has had others within last two years.		F.	31	5	" "
14.	Two discrete glands under sternomastoid. Old scars from others.		M.	7	1, 3	Reaction after 3 mg.
15.	One discrete submaxillary gland.	2 wks.	F.	23	5	Reaction.

20.	One gland in left neck.	1 wk.	F.	12	1-2, 1, 2	" "
21.	Scar from old gland in left neck.		F.	7	1, 2	No reaction.
22.	Glands in left neck; has had others.	8 mos.	F.	16	3	Reaction.
23.	One large gland below angle of left jaw; has had others.	6 yrs.	F.	14	3	"
24.	Three large fluctuating glands in left neck; has had others.	6 mos.	M.	27	5	"
25.	Glands in right neck.	8-9 yrs.	F.	21	5	"
26.	Glands in right neck.		F.	18	3	"
27.	Enlarged submaxillary gland, left side.	2 wks.	F.	19	5	No reaction.
28.	Glands in left neck and in left axilla.	2 yrs.	F.	20	3	Reaction.
29.	Enlarged submaxillary gland, left side.	1 wk.	F.	35	3	No reaction.

brief, whatever strengthens the resisting power of the individual. Although I have never been convinced that creosote has any specific action in tuberculosis, I do believe that it does raise the level of the patient's resistance and aids nutrition however this may be accomplished, and therefore I use it either alone or in connection with cod-liver oil and malt. So long as tuberculous glands exist they are always a menace to the individual, and consequently the logical treatment is their excision if this can be accomplished. Failing in this I should let them alone if they are not suppurating and devote my exertions to the general treatment. If they are suppurating, the sooner they are drained and healed the better—with the Briggs' cannula, or a seton, drainage can be expeditiously accomplished. Filling the cavity with iodoform emulsion after drainage from a small opening is also a valuable method. In a considerable experience I have never seen many, if any, favorable results from external applications. I may as well append here a series of tuberculin tests of various random cases (Table II.), made at the same time as the others, being rather of the nature of control cases, especially those of inguinal adenitis known to have had their origin in venereal infection. In the six cases of bubo, none gave a positive reaction. One of them gave what I have indicated as a probable reaction; possibly there was a tuberculous focus elsewhere if the reaction actually occurred. The results in most of the other cases corroborate the clinical diagnosis. In the three cases of pulmonary tuberculosis proved to be such by the presence of tubercle bacilli in the sputum, it will be noticed that in only one was a reaction obtained. A possible explanation of this one, in which the disease was quite extensive, may be that the system had been rendered immune by the dissemination of the disease itself. Other observers have reported a similar result in certain cases of extensive or advanced phthisis; possibly a larger dose of tuberculin than the one used—five milligrams—may have been required in this case. Where the error was, or why there was no reaction in the other case, I am unable to say.

TABLE II.—GENERAL CASES.

No.	Diagnosis.	Age.	Dose in mg.	Result.
1.	Suppurating inguinal gland.	28	5	No reaction.
2.	Suppurating inguinal gland.	34	5	" "
3.	Suppurating inguinal gland, both sides.	33	5	" "
4.	Suppurating inguinal gland, left side.		10	" "

6.	Suppurating inguinal gland, right side.	42	10	Probable reaction.
7.	Enlarged gland, r. axilla.	14	3	No reaction.
8.	Enlarged glands, l. axilla.	40	3	Slight reaction.
9.	Suspected tuberculous wrist, also complains of cough and says she has spit blood.	16	1	Reaction.
10.	Indurated swelling of the right testicle, 1-month's duration; no known cause.	29	5	Reaction.
11.	Indurated swelling of the left epididymis of 3-yr's. duration.	24	5, 10	No reaction.
12.	Swelling of right wrist, possibly tuberculosis.	26	8	Reaction.
13.	Arthritis of carpometacarpal joint of r. thumb.	23	5	No reaction.
14.	Old sprain of ankle.	21	5	" "
15.	Necrosis of right thigh.	23 mos.	1	" "
16.	Chronic laryngitis; specific.	26	10	Moderate reaction.
17.	Atrophic rhinitis; pharyngitis sicca.	21	5	Reaction.
18.	Atrophic rhinitis; pharyngitis sicca.	36	5	Moderate reaction.
19.	Recent injury to side.	60	5	No reaction.
20.	Abdominal ascites, 10 months.	19	5	Doubtful reaction.
21.	Pulmonary tuberculosis, quite extensive consolidation; tubercle bacilli in sputum.	50	3, 5	No reaction.
22.	Pulmonary tuberculosis, atrophic rhinitis; tubercle bacilli in sputum.	24	5, 10	No reaction.
23.	Pulmonary tuberculosis, slight consolidation; tubercle bacilli in sputum.	24	5	Reaction.

In this series of cases also, no injurious effects or untoward results were observed from the use of the tuberculin. From the experience then, in these fifty-three cases, I have decided that it is a safe procedure and that one need not feel apprehension in its employment. Further, I believe that it is a valuable and easy diagnostic method in many and various conditions in which a suspicion of tuberculosis exists, and would commend its use. I have to acknowledge my indebtedness to those of my colleagues at the Boston Dispensary who kindly assisted me with clinical material, and also to Dr. F. W. Peare for his continued aid throughout the entire series of experiments.

ERYTHROPSIA; REPORT OF A CASE FOLLOWING AN OPERATION FOR CATARACT.

BY GLENDON E. CURRY, M.D.,
OF PITTSBURG, PA.;
ASSISTANT OPHTHALMOLOGIST TO MERCY HOSPITAL.

MINOR degrees of erythropsia or red sight doubtless are more frequent than is generally supposed. The condition is usually noted in eyes which have been operated upon for cataract, and often being of but momentary duration, and developing, as a rule, after the patient has been discharged as recovered from the result of the operation, leaves but little or no doubt that in many instances this symptom is not mentioned or complained of by the patient, and thus not brought to our notice.

Erythropsia may occur subsequent to other opera-

tions upon the eye, as in iridectomy; it has also been observed in eyes which have not been subjected to operation at all, but less frequently. The development of this phenomenon usually takes place after the eyes have been exposed to some brilliant or dazzling light, and perhaps the most frequent cause in eyes which have not been operated upon is the dazzling light reflected from a large surface of fallen snow, although it may be produced by the eyes being subjected to any glaring light, as after observing a sun eclipse, or can even come on after over-heating of the body. Erythropsia produced by dazzling from snow occurs more frequently in high altitudes. In Artic regions, where there is much snow-blindness, but where the elevations are slight it is not observed. Fuchs,[1] however, demonstrated that by allowing more light to reach the retina by dilating the pupils, and then there being an exposure to snow, it would occur just as often at low altitudes as in high ones. The congestion occurring in overheating, after eating, dancing, in suppression of the menses, in anger, etc., are only predisposing factors to the development of the condition, as there must be an excessive reaction of the retina to light in addition to bring it about. Atypical forms may be present, as in an epileptic aura, or where there is an intra-ocular hemorrhage giving rise to red vision. An interesting case mentioned in history is that of Henry IV. of France. While playing chess on the eve of St. Bartholomew's massacre, the chessmen appeared red.

The onset of erythropsia is usually abrupt, the patient suddenly observing everything to be of a vivid red color, the duration of the sensation varying from a few minutes to several hours. It is quite apt to recur frequently, and apparently does no harm to the visual power of the eyes.

On January 8, 1896, I performed an operation for the extraction of a cataract from the right eye of P. C., aged sixty-eight years. The operation was the combined one, or extraction of the lens with an iridectomy. There was no accident or complications at the time of the operation, and the healing of the wound was good and prompt. About four o'clock one evening, early in March, the patient observed that everything suddenly became of a vivid red hue, and remained so until night. The next morning this phenomenon was not present, but again appeared at about four o'clock in the afternoon. Some days it was absent altogether, but appeared every three or four days at most, and always between 4 and 6 P.M. At first the color was an intense red, but gradually shaded off, becoming a lighter and lighter tint of red until about May 15th, or two and one-half months after it was first observed, it was no longer noticeable, nor has it appeared since. When the erythropsia first became manifest there was snow on the ground, and the patient had been out in the open air and his eye was exposed to the reflection of the light from the glaring surface of the snow for several hours, and this seems to have been the exciting factor in the causation of the condition. The vision in the eye equalled two-thirds ($\frac{2}{3}\frac{0}{0}$) with a proper glass, and Jäger No. 1 type was read without hesitation. At no time was the acuteness of the vision interfered with by the erythropsia.

Fuchs' thinks the glare is the sole factor in producing erythropsia, and that the seat of the phenomenon is in the retina. Schulek[2] believes that the cause is not entirely in the retina, but in a measure in the primary brain-cells. He states that the phenomenon appears because the ultra violet centers become tired and allow an over action of the red centers, and defines erythropsia as a regenerative condition of the red-green sight substance caused by photochemical irritation, which has created a condition of exhaustion in the brain-cells.

Another theory advanced, by whom I am unable to recall, is that erythropsia is caused by the active regeneration of the visual purple under the influence of a strong light stimulus. Certainly the glare is largely concerned in bringing about the condition, as it is scarcely ever observed where glare is absent, and is of comparatively frequent occurrence where people are obliged to travel over fields of snow. It has been noted in many cases that the point of fixation, corresponding to the macula, does not appear red, and when at all only after there has been exceedingly strong excitation. The cones of the layer of rods and cones of the retina cannot be the seat of the phenomenon in such instances, as they do not contain the visual purple, and the rods, which alone possess this substance, do not exist in the macula. If we accept this theory, a strong light stimulus acting upon the rods (as they alone contain the visual purple) inducing an active regeneration or excess of formation of the visual purple, is probably the principal etiologic factor in erythropsia. Dr. Greef[3] of Berlin reported a case of erythropsia in which the patient could only distinguish between red and black. No other color was perceived. Here other factors were probably concerned in the etiology.

The salient features of the case reported were the appearance of the erythropsia following an exposure to the glare arising from a large surface of snow; it was more intensely red at first, gradually fading, and ultimately disappearing entirely; it was always manifest at about the same hour, and it occurred in an aphakic eye. For some days before and after the appearance of this red sight the ground was cov-

[1] Graefe's "Archivs," vol. xlii, October, 1896.

ered with snow, and the patient was out more or less each day, and not protecting his eyes specially from the dazzling reflection from the glaring surface of snow, and the fact that the eye was a post-operative one, more light reaching the retina through the coloboma than was usual, leads me to conclude that these were the only factors concerned, in this instance, in bringing about the condition.

NON-MALIGNANT STRICTURE OF THE RECTUM.[1]

BY A. E. HALSTEAD, M.D.,
OF CHICAGO;
PROFESSOR OF RECTAL SURGERY IN THE CHICAGO POLYCLINIC; INSTRUCTOR IN THE PRINCIPLES OF SURGERY AND CLINICAL SURGERY IN THE NORTHWESTERN UNIVERSITY MEDICAL SCHOOL OF CHICAGO.

A NON-MALIGNANT stricture of the rectum may be defined as a pathologic condition in which there is a progressive narrowing of the rectal canal following a loss of tissue, the result of ulceration or of trauma, and the subsequent contraction of the inflammatory tissue. As causes of the local conditions producing rectal stenosis we have syphilis, trauma, simple ulceration, gonorrheal and chancroidal ulcers, dysentery, phlegmonous proctitis, and tuberculosis as active factors. Syphilis is the most frequent cause, and one-third of all cases may be attributed to it. Curling in twenty cases of stricture found nine which he ascribed to obstetric trauma. Strictures have followed operations for hemorrhoids, fistula, and prolapsus recti. Cripps in seventy cases found one of tubercular origin. In the "Medical and Surgical History of the Rebellion" there is not a single case recorded in which stricture followed dysentery.

Stricture is more common in the female than in the male sex, in the ratio of three to one. Penet studied post-mortem the location of stricture in fifty-eight cases, and found them situated at the following distances: Commenced at the anus in four, below 6 cm. (2½ inches) in thirty-two, at 6 cm. in three, between 6 and 9 cm. (3⅜ inches) in seven, above 9 cm. in five, and at the junction of the rectum and colon in five.

The symptom first noticed is constipation alternating with diarrhea, or the discharge of bloody mucus. Vomiting, anorexia, and emaciation, accompanied by hectic fever, with headache and vesical disturbances, are among the later symptoms; acute and complete obstruction is rare, the patient generally dying from exhaustion or some intercurrent disease before this occurs. A positive diagnosis can only be made after a local examination. Treatment may be by dilatation, electrolysis, internal and external proctotomy, inguinal or lumbar anus, plastic operations, anastomosis, and excision, perineal or sacral. The treatment by perineal excision or resection, after Dieffenbach and Volkman, or as Van Hook has termed it, modified amputation of the rectum, is the best method of treating non-malignant rectal strictures which are not situated above the peritoneal level.

As an argument in favor of the superiority of this method, and as a means of describing the technic, I report two cases of rectal stricture in which permanent cures were attained by amputation of the strictured portion of the gut.

CASE I.—Mrs. A. J. B., aged thirty years. Nativity, Irish. Was admitted to the Cook County Hospital, March 28, 1895. Family history negative; married ten years. Seven years before she had a premature labor; not been pregnant since. Shortly after marriage she contracted some kind of "blood" disease, which caused loss of hair and a cutaneous eruption, for which she was treated two months. About six years before admission to the hospital she began to have symptoms of rectal disease. At first she noticed a bloody purulent discharge from the bowel associated with considerable pain and tenesmus on defecation. About one year after the appearance of the first symptom she became aware of increasing difficulty in having a bowel movement. At the time I saw her her bowels moved about once a week, and then only after repeated efforts. At such times a large quantity of fluid feces, blood, and pus was discharged. About one year before a fistula had opened on the buttock at the left of the anus.

The patient was greatly emaciated, pallid, and very weak. Numerous copper-colored scars were distributed over the body; lymphatic glands moderately enlarged; heart and lungs negative; abdomen distended. Patient complained of constant pain over the whole abdomen, and marked tenderness in the right iliac fossa.

Rectal examination showed a large ulcer just above the anus mostly on the posterior surface of the gut. Above the ulcerated area, at a distance of 1½ inches from the anus, was a circular constriction, which would just admit the tip of the finger, but through which the finger could not be forced. On examination with a sound it was found that a No. 28 (French) urethral sound would just pass through the strictured portion of the gut. On vaginal examination, the upper limit of the stricture could be felt, which showed it to be of the annular variety, about one inch in length. One inch to the left, and a little behind the anus, there was a fistulous opening from which was discharged bloody pus. A sound passed into this fistula apparently passed into the rectum above the stricture, and could be felt through the recto-vaginal septum.

A few days after admission an incision was made, laying open the fistulous tract, and completely dividing the stricture and posterior wall of the rec-

[1] Read before the Illinois State Medical Society.

tum. The sinus was then thoroughly scraped with a sharp curette, the bowel washed out with sterile water and the wound packed with iodoform gauze. Rapid improvement in the patient's general condition immediately followed, the pain disappeared, the appetite improved, and the temperature became normal within a few days. At the end of six weeks a radical operation was attempted. The wound had almost healed by granulation, and ulceration had nearly disappeared. The patient was placed in the exaggerated lithotomy position and the part exposed by stretching the sphincter, which, of course, reopened the wound in the posterior rectal wall. The rectum was then denuded of its mucous membrane from the mucocutaneous junction to the lower limits of the stricture. This dissection was carefully made so as to avoid injuring the underlying sphincter. The hemorrhage at this stage was profuse, but was easily controlled by pressure and hemostatic forceps. The rectal wall was now divided throughout its entire circumference at the lower limit of the stricture, and by careful dissection the entire cicatricial mass was separated from the surrounding tissue. During the process of separation traction was made on the strictured portion of the gut, so that when the mass was entirely free it protruded beyond the anus. The rectum was then amputated just above the stricture, and the cut end attached to the skin, first by three deep sutures, and then by a row of superficial intermediate sutures. A rubber tube six inches in length and three-fourths of an inch in diameter, wrapped in iodoform gauze, was introduced into the rectum, while gauze drainage was placed in the wound and an ordinary antiseptic dressing applied. The after-treatment consisted in frequent change of dressings, liquid diet, and keeping the bowels inactive for one week. The patient left the hospital about six weeks after the operation, apparently in perfect health. Twenty-one months after the operation she was still enjoying good health without any return of the stricture, and with excellent control of the sphincters.

Case II.—Mrs. E. J. S., American, aged thirty-four years; married. Consulted me in January, 1894. Family history negative. Married fourteen years; had had two children, the elder being twelve and the younger ten years of age. Venereal disease denied; never had any illness excepting that which followed last confinement, and which was said to have been puerperal fever Present illness began about three years before, with pain and tenesmus on defecation, accompanied at times by discharge of large quantities of pus and mucus. Constipation gradually became more and more troublesome, until only by the constant use of cathartics could the bowels be moved. One year after the first symptoms were noted she consulted a physician who recognized the condition and treated her for nearly a year, by passing graduated bougies. Under this treatment, and with careful regulation of the bowels and diet, she improved. At the end of this time she went to reside on a farm where she could not get proper treatment. Her condition rapidly grew worse, all the old symptoms returning in an exaggerated form. At the time that I made the first examination she appeared greatly emaciated and very weak. The skin was somewhat jaundiced and the tongue heavily coated; pulse was accelerated; the temperature slightly above the normal. The abdomen was greatly distended and somewhat tender on pressure. Rectal examination showed an annular stricture beginning about 1¾ inches above the anus, and involving as near as could be determined, by vaginal examination, about 1¼ inches of the bowel. The stricture barely admitted the tip of the examining finger. Treatment by gradual dilatation was immediately employed. This, with regulation of the bowels and diet, again produced marked improvement. After six months of treatment, the patient unfortunately was forced to leave the city. During an absence of four months, all treatment was discontinued, with the result of a return of the symptoms. At the end of this time, on returning to the city, she readily consented to an operation, with the hope of having permanent relief. In October, 1894, I operated, removing the strictured portion of the gut, as in the case above reported. This was followed by complete recovery. When last seen, one year and three months after the operation, there were no signs of a return of the stricture, nor had she any inconvenience.

DIABETES MELLITUS.

By H. G. NORTON, M.D.,
of Trenton, N. J.;
visiting physician to St. Francis and Mercer Hospitals.

It seems to me that diabetes is on the increase. Just why I am unable to say; possibly the great amount of sugar and starch consumed may account for it. The following nine cases now under my care would seem to indicate that the disease is abroad, if looked for. I cannot recall a time when I have not had some cases, but never so many as now. I do not believe as many cases are met in the country as among city dwellers. I make it a habit to examine the urine of nearly every patient under my care, which may account for the number of diabetics now among my patients. I am certain of my tests and my solutions. Usually I permit the specimen to be examined to stand twelve hours or more to allow any uric acid to settle, using the upper strata for examination. A drop of muriatic acid added to the urine will more quickly precipitate the uric acid. When the urine is scanty and high-colored, according to Tyson, it is always best to eliminate this source of error by adding hydrochloric acid, making sure that the urine is again made alkaline before being tested.

Case I.—Female, stout, single, aged sixty-five years. In good circumstances. Always a very careful and proper liver. Is losing flesh, her hair is falling out, and she shows signs of general impairment of health. Is not very careful as to her diet,

and is not holding her own She has pruritus vulvæ at times.

CASE II.—Female, stout, married, aged seventy-five years; mother of five children. Is in good circumstances. A full feeder. I was led to examine this patient's urine because of a history of ineffectual attempts to cure an obstinate attack of pruritus vulvæ. Careful dieting soon removed the intolerable itching, and she is doing well on a moderately strict diet.

CASE III.—Female, Hebrew, stout, married, aged forty-five years; has had one child. Is in good circumstances. Dieting and treatment do not diminish the amount of sugar much, but she is not losing weight.

CASE IV.—Male, colored; a clergyman; medium weight; married; aged forty-five years. In good circumstances. Has extreme thirst and polyuria.

CASE V.—Male, stout, married, aged fifty-six years. In good circumstances and a free liver. Has lost seventy pounds since last spring. Strict dieting has nearly removed the sugar from his urine, and he is gaining in flesh. I have allowed him to gradually resume his usual diet, except sugar, sugary fruits, and grapes.

CASE VI.—Male, stout, married, aged sixty years; saloon-keeper. In good circumstances, free liver, and moderate drinker. Has eczema of legs, itching, and soreness of glans penis and prepuce, accompanied by great thirst. He is always improved by dieting.

CASE VII.—Male, stout, married, wealthy; aged sixty-five years. Has had but little treatment, and is holding his own.

CASE VIII.—Female, stout, married, aged thirty-three years. Mother of four children. In good circumstances. Found sugar in her urine during her last pregnancy, which she passed through uneventfully, except that her getting up was slow. Neither dieting nor the termination of pregnancy have removed the sugar.

CASE IX.—Male, stout, married, aged forty-five years. Has lost flesh. Dieting and treatment do not remove the sugar, but improve his general health.

Analysis of these cases shows five men and four women, all stout or inclined to stoutness, except the negro, all among the well-to-do, and free livers, none being of dissipated habits. My patients usually soon tire of a strict antidiabetic diet, and I find the various diabetic flours to be a poor substitute for ordinary wheat flour. As to treatment, I find that Fowler's solution and codein give me the best results, together with tonics, such as muriatic acid, strychnin, and quinin, as indicated. Some patients are glad to use saccharin, while others dislike it.

Among the diabetic patients formerly under my care was one boy, six years old, who died after a brief illness, no remedy or dieting seeming to have the slightest influence on his disease. He rapidly passed into a comatose condition and died. His mother was an extremely neurotic woman, who died of consumption afterward.

I have amputated the limbs of several patients for diabetic gangrene, nearly always with fatal results. I recall these cases: (1) Amputation of leg at lower third for gangrene of foot; died. (2) Amputated arm at middle third for gangrene of hand; died. (3) Negro; amputated leg above knee for gangrene of foot; recovered. (4) Negro; amputated toe for gangrene; recovered. After two or three years he returned with gangrene of the other toes and a deep ulcer over the external malleolus. His condition did not then seem to warrant an amputation, and he died a few days later.

WAR ARTICLES.

NEWS OF THE WEEK.

THE terrible loss sustained by the American forces in the recent battles before Santiago inclines one to wonder if the result would not have been different had General Shafter but waited, as it was expected he would do, for the reinforcements now on the way, and for additional artillery. According to the latest despatch as we go to press, "There is but little sickness outside of exhaustion from the intense heat and the exertion of the battle. The behavior of the troops was magnificent," but a thousand men were either killed or wounded! It is fortunate that the hospital ship "Relief" will so soon be at hand to assist the "Solace" and "State of Texas" in transporting the wounded to the well-equipped military hospitals in Florida, for even with the attendance of the Red Cross and other nurses, a seriously wounded soldier, with the prospect of a long illness before him, would have to battle against strong odds in the enervating climate of Cuba, no matter how favorable his surroundings might otherwise be.

. . . . . .

It is not generally known that the "Relief" is a medical and surgical supply-ship as well as a hospital ship. Her ice-manufacturing plant will produce two tons of ice per day, and with her distilling apparatus she can turn out 1500 gallons of pure water per day. In her sick wards she has 360 beds, but in addition carries 750 folding cots and 650 extra mattresses, so that almost any requisition from the field surgeons in Cuba can be filled without delay. Her supply of delicacies, wines, medicines, dressings, etc., is most abundant, and almost entirely made up by voluntary offerings from patriotic citizens in all parts of the country.

. . . . . .

The experience of our soldiers in the tropical cli-

mate of Cuba has necessitated a modification of Artemus Ward's graphic description of a hot-weather costume. Instead of "a shirt collar and a pair of spurs," which Artemus, if we remember rightly, recommended as a comfortable Kentucky outfit, our boys are reported as fighting valiantly in "a cartridge-belt, a chew of tobacco, and a smile." Flannel coats, blankets, etc., were dropped along the line of march, as their burden became utterly insupportable, and were promptly appropriated by the insurgents, the majority of whom are in rags, and who will doubtless find some way of saving the warm clothing for the cold season.

. . . . . .

The hot, humid weather of the past week, as experienced so generally throughout the United States, gave us just a sample of what our men are enduring at Santiago, and the light canvas suits, weighing about three pounds each, which have already been sent to them, will be a most timely and welcome relief. Twenty-four thousand of these lightweight canvas uniforms are already well on their way to the Army of Invasion.

. . . . . .

So far the elements have been with us. The dreaded rainy season has held off to such a degree that our men have kept in good condition, with very few exceptions. Our lucky star guided Admiral Cervera into Santiago harbor, and as a result the Army of Invasion was sent to the hill country in this neighborhood where the air and soil are infinitely more healthy and endurable to our Northern-bred men than the swampy lowlands surrounding Havana, where a month ago it was supposed the first United States camps on Cuban soil would be located.

. . . . . .

Our Board of Strategy seems so destined to make plans which unexpected circumstances cause to gang aft-agley, that it now appears only to be necessary for our Army and Navy to stand ready to take advantage of the blunders of the enemy.

. . . . . .

At the present writing Admiral Camara's pleasure trip with the Cadiz squadron has extended to the Suez Canal, and he is evidently pausing to mark the effect of his "bluff." Camara will surely go down in history hand in hand with that doughty warrior who "marched his soldiers up a hill and then marched them down again."

. . . . . .

And now the International Temperance Congress just assembled at Prohibition Park, Staten Island, suggests that candy or other sweetmeats and cake should not be sent to the soldiers because they are apt to produce a thirst, which may possibly be quenched by intoxicating drinks! We speak from slight experience, but we have always thought that a thirst engendered by eating sweets called for water, and water only.

. . . . . .

A welcome addition to the soldier's outfit will be the mosquito-proof tents which are to be sent to Cuba, Puerto Rico, and Manila. The tent is a small affair, made of fine, white cheese-cloth, may be readily carried in a knapsack, and weighs one and one-half pounds. When opened it is five feet high, six feet long, and three feet wide. It affords ample protection against mosquitoes, flies, insects of all kinds, and dew.

THE WOUNDED OF "ROOSEVELT'S ROUGH RIDERS."

FLAGSHIP "NEW YORK,"
OFF SANTIAGO, CUBA, June 30, 1898.

ON June 24th the Rough Riders were sent out ahead on scout duty on the advance of the army upon Santiago. The country is very hilly and is covered with brush, and is almost impassible in places. Suddenly the Americans were made aware of the presence of the enemy by a fierce musketry volley that came from an ambuscade. Our men immediately fell flat on the ground and began to fight in Indian fashion, shooting only when they saw a Spaniard. The enemy fired at random, and, as one of the Riders said, if we had been hit as often with bullets as we were with leaves there would have been nothing left of us.

The Americans, although outnumbered, advanced steadily, going forward by short dashes when the opportunity offered, then falling flat on the ground to fight again. The wounded, such as were able, were told to walk to the camp at Siboney, a distance of four miles. When they arrived there the first seven were sent to the U. S. S. "St. Louis" for treatment. One man had been struck three times, once in the neck by a lead bullet, which was removed, the second and third wounds having been produced by Mauser bullets, one passing through the muscular tissues of the left forearm, the other entering his body near the coccyx, and passing through the gluteal muscles. Neither of these wounds presented laceration, but were of the simple punctured variety, the wound of exit being larger than the wound of entrance. There was considerable laceration in the neck wound.

Another man was shot, probably by a forty-five-caliber brass-jacketed lead bullet through the back of the right forearm. There was considerable lacera-

tion of muscles and tendons, and a small piece of the radius was chipped off. The wound was large and gaping. The parts were trimmed up, the muscles and tendons sewed together, and the wound closed without drainage, the arm being placed on a splint.

The most interesting case from a surgical point of view was that of a man who was shot by a Mauser. He was struck as he was making a dash forward. The ball entered the dorsal aspect of his penis just to the right of the base of the glans, proceeded backward and to the left, injuring the lower portion of the urethra, then entered the superior portion of the scrotum, went downward through the left testicle and out of the scrotum on its inferior surface and grazed the inner side of his left thigh. This man had walked four miles after receiving the wound. When he arrived on board the "St. Louis" he was placed on the operating-table. As his penis was very much swollen and black from effused blood, as was also the scrotum, and as he had a marked phimosis, a circumcision was performed and his urine drawn with a metal catheter. The catheter could be felt with a probe through the bullet wound and fluid injected into the meatus ran out of the lower wound, showing that the urethra had been partly severed. The urethra was distended with a number twenty-six French bougie and its floor repaired with a double row of sutures. A soft rubber catheter was left in the bladder and the scrotal wounds drained with iodoform gauze. This patient also had two punctured wounds of the forearm, neither of which showed any laceration.

One man received a Mauser bullet through his left ring finger. The ball knocked a little piece of bone off of the second phalanx and cut the skin and tissues on the side of the digit. There was one punctured wound of the soft parts over the scapula and another punctured wound of the soft parts of an arm. Both were produced by Mauser bullets and neither showed any laceration. Some of the injured men said that when they were hit it felt as if they had been stuck with a pin; others said they felt nothing and only became aware of their wounds by seeing blood. The range at which all these injuries were received was very short, probably between fifty and one hundred yards, yet contrary to expectation there was no lacerating effect produced by the Mauser bullet.

One of the first questions asked by almost every one of the wounded Riders was, "Doctor when will I be able to get into it again?" All seemed anxious to get back to their companies. None murmured when their wounds were being dressed, and all refused whisky when it was offered to them. When the Spaniards realize what plucky men they are fighting against they will talk less and think more.

RAYMOND SPEAR, M.D.,
Assistant Surgeon, United States Navy.

DISEASES COMMON TO THE PHILIPPINES: KAKKE, OR BERIBERI; DYSENTERY. POISONOUS SNAKES. MANILA IN TIME OF PEACE.

[From Our Special Correspondent.]

With Commodore Dewey's Squadron off Manila, Philippine Islands, May 15, 1898.

BY the time this reaches you the details of the battle of Cavité will have been fully reported by the daily press in America, and therefore I need not spend time in giving you an account of our inconsiderable casualties. Since the memorable events of May 1st, Commodore Dewey's squadron has been to a great extent inactive, the only occurrences of importance having been the occupation of Cavité by the marines, the occasional despatch of one of the ships to intercept a suspected blockade-runner, and the exchange of courtesies with a foreign war-vessel. The "McCullough" is expected hourly from Hong-Kong with dispatches from Washington and I hope to be able to send this letter by her on her return trip. Naturally there is not much to write about under the circumstances, but it occurs to me that a few words about Manila and the Philippines in time of peace may prove of interest.

It is very hot here, but the men are all in buoyant spirits and speculation is rife among them as to what the next move is to be, and whether reinforcements will arrive before the final attack is made on Manila. The health of the crews continues good, but while the American soldiers in their occupation of the Philippines will not be subject to the danger of yellow fever which threatens the army in Cuba, there are other diseases prevalent in Manila and vicinity worthy of consideration. The population of the city of Manila with its outlying wards is only about 250,000, yet the average number of inmates in the leper house is two hundred, and there are other lazarettos in different parts of the island. Two severe epidemics of cholera have visited the city during the last century, one in 1820 and another in 1858; but the danger of another outbreak of the disease in the immediate future is too remote to be considered. Dysentery, which is so deadly in some of the islands of this group, is less frequent and less virulent in character in Manila and other parts of the island of Luzon, though many deaths occur from it every year. The flannel bandage over the abdomen, habitually worn by the British soldiers in the tropics, and by many other Europeans here, is a

great preventive of dysentery and other intestinal disorders. One of the principal causes of the disease in this climate is bad water; but since about the year 1884 Manila has had good drinking-water, though the European doctors often insist on its being boiled.

During the rainy season, which begins about the first of July and lasts until the end of October, there are many cases of malarial and other fevers, and a form of malaria closely resembling typhoid is quite common in the city, especially at the beginning of the rainy season; but the marshy country around Manila is comparatively free from it. Epidemics of smallpox and measles are of almost yearly occurrence, and there are many deaths from the former though the latter is comparatively mild.

Among the native and Spanish troops syphilis is shockingly prevalent. In the military hospitals about twenty per cent. of the inmates are generally found to be suffering from this disease. Tuberculosis and bronchitis are very common among the natives, and in the military hospital in Manila a great many cases are always to be found. It has been asserted that seventy-five per cent. of the native troops in the hospital have one or the other of these diseases.

There is a peculiar disease often met with in the Philippine Islands, and also in China and Japan. The Japanese call it *kakké*, and from the ancient writings of Chinese physicians it appears to have existed in that country for centuries. It is commonly known as beriberi, and its victims are generally men between twenty and thirty years of age. It attacks both sexes, but women are much less susceptible to it than men. It is essentially a nervous disease, a neuritis, a kind of muscular paresis, and its symptoms are very puzzling to the novice. At different times it has been diagnosed as muscular rheumatism, locomotor ataxia, heart disease, Bright's disease, etc. There have been several epidemics of beriberi in the jail at Hong Kong, and it sometimes attacks British soldiers in these latitudes. Occasionally an isolated case is found aboard ship, and epidemics are not uncommon. Its victims are particularly liable to sudden death from paralysis of the heart, or of the muscles of respiration, edema of the lungs, or a combination of these conditions. Its most prominent symptoms are numbness of the feet, legs, and finger-tips, weakness of the muscles, difficulty in breathing, and palpitation of the heart. There are often painful cramps in the muscles of the calf and thigh. An attack is generally preceded by a period of restlessness and inability to perform customary work. The legs and knees of the patient are weak and he frequently has headache and chills. The face may become puffy and bloated and there may be other dropsical symptoms. He may suffer from these symptoms off and on for several weeks before becoming positively ill. With all the conflicting symptoms of this many-sided disease there are two which are never absent: numbness of the shins, and tenderness of the calves of the legs. The numbness often extends to the thigh and is felt in the arms and hands, especially in the finger-tips. If the case is severe, in a few days the patient may be unable to move about. The senses of sight, hearing, taste, and smell are generally unaffected, though the patient is incapaciated for any mental effort. There are two forms of beriberi, the dry and the wet. In the case of the former there is great emaciation, and often in an incredibly short time the body of the sufferer is reduced almost to a skeleton; in the case of the latter, the body is swollen and looks like one that has been several days in the water. Beriberi generally attacks its victims in the wet or hot weather; in the cold season it is practically unknown. It sometimes becomes chronic, returning periodically with the hot weather. After partial recovery, the muscles of the calf are sometimes shortened, so that the patient walks on his toes. Beriberi is generally recognized as a germ disease, but practically nothing is known of the germ itself. It is supposed to be indigenous to certain soils, as it exists only in particular localities, though this fact has not been positively established.

There is a strange affection which appears among the cattle of these islands. It is said by the natives that the internal organs of an animal affected by this disease turn to blood, and in an epidemic which occurred a few years ago one man lost eighty-five per cent. of his live stock. Personally I have not seen a case of this peculiar complaint, nor do I for the moment remember its name.

The European residents here complain of a tendency to scruff, which develops after a short stay in this climate, but they are generally loth to adopt the national preventive. In the forests of Luzon are a great many monkeys, and there is a belief among the natives that stewed monkey is an unfailing cure for all cutaneous diseases. To the stranger in these islands the idea of eating monkey-flesh may be very revolting, but there are few dishes more delicate than the young monkey stuffed and baked, though it does look very much like a small brown baby.

The cities, as well as the jungles, abound in insects, reptiles, snakes, frogs and lizards, land crabs, centipedes, tarantulas, huge poisonous spiders, locusts, beetles, and ants. Of all the snakes the ones most dreaded are those the natives call the *alupong*

and the *daghong-palay*. The bite of either of these is fatal if not cauterized immediately. The *daghong-palay* is found in the deep mud of rice-fields, and among the tall rice-blades. Every pool of stagnant water is alive with leeches, and in the forests there is a tiny leech which has a disagreeable habit of unexpectedly jumping into one's eyes. Swarms of ants are found everywhere. Some of them are the size of a pinhead, others are half an inch long, and they are so destructive that sometimes whole warehouses have to be torn down because of their inroads. They can eat through any wood except the very hardest.

In the Philippine rivers are huge caymans that are very cruel and bloodthirsty. The natives fear them so much that in cursing an enemy they say, "May the cayman kill him!" and there is a superstition among them that if they swear falsely, or break their promises, the cayman will kill them, and they can always cite instances in which this fate has happened to wrong-doers. In Manila mosquitoes are very troublesome; but there are few crawling insects about, for the reason that they are destroyed by the newt and a species of lizard called *chacon*. The newt is a strange little reptile, and if one is caught by the tail he shakes it off and runs away without it. At night huge bats fly about overhead, and these nocturnal visitors inspire the greatest horror in one who does not know what they are; for they often measure five feet from tip to tip of their wings. Bat-shooting is considered fine sport among the young men in the Philippines, and those who were compelled to stay long in Manila in antebellum days were glad of any form of amusement, for ordinarily it is a dull city, though the girls are said to be the most beautiful in the world. There are no popular cafés, no opera house, and absolutely no place of recreation. Not until 1887 were there any gardens in the public squares. The streets are narrow and badly lighted by petroleum lamps, and in the suburbs cocoanut oil is sometimes used for that purpose. The paving is wretched, and during the wet season it is almost impossible to get about. In the wards occupied principally by the poorest working-classes, huts with thatched roofs are still constructed, and the only drainage in this part of the city is by ditches cut around each square. In the wet season this district is a mass of pollution, many of the huts having pools of stagnant water under them for months. When the rains stop and evaporation commences, fever breaks out among these wretched people and many of them die.

Down in the city itself the conditions are somewhat better, and a foreigner could make himself fairly comfortable, for there are several Spanish hotels where the fare used to be decent, but the beds and other accommodations are very bad. Very few of the houses have more than the ground story and one upper floor. The former is so damp that it is used generally for lodging the native servants and for a coach house. Manila is not a place that would be chosen as a residence by a person looking for pleasure and comfort. The climate is very trying, except for about four months in the year, and a typhoon comes along occasionally and makes things lively for awhile. Manila's population of 250,000 is composed about as follows: Sixty-seven per cent. pure natives, thirty per cent. Chinese and Chinese half-breeds, and three per cent. Spanish and a few other Europeans. It is within the last hundred years that the Spanish soldiers were so badly and irregularly paid that they used to go begging from house to house about the city. I presume from present indications that before this letter reaches you, if Commodore Dewey continues to maintain the blockade in the present effective way, the officers and even the Governor-General will become accomplished mendicants as well. The entire male population over sixteen years of age are compelled to carry arms and consider themselves in the military service. There is a medical board, composed of European Spaniards, that has general supervision over the troops. The military hospitals are subject to the authority of this board, which nominates an officer to each of the regiments. This officer is called an *agudante*.

In America we often hear doctors complain of the fierceness of competition among the members of the medical profession, but in Manila there is a mob of third-rate native doctors who manage somehow to eke out a poor existence. They are mostly sons of ambitious natives who are anxious to see their children launched in the "learned professions."

It is to be hoped that whoever has charge of the commissary department of the American army will avoid tinned provisions and use fresh food whenever possible, for in this climate tinned meats spoil very soon and the cans become bulged, which shows that the contents are not fit to eat. Foreign residents in Manila generally find the meat of indifferent quality; but poultry in times of peace is cheap and plentiful. Cocoa is a much better tropical drink than either tea or coffee. Fruit is plentiful here and wholesome, if eaten in moderation; but the old adage, "fruit is gold in the morning, silver at noon, but lead at night," is particularly applicable to those who live in hot climates. There are many tempting-looking fruits and berries growing in these islands that are very poisonous, and one is never safe in eating unfamiliar fruits.

It takes some time for the American to become acclimated in the Philippines, and the United States

soldiers will find conditions here very different from anything to which they have been accustomed in the United States. Many cases of sunstroke among the troops are to be expected and they may find it hard at first to restrain their Yankee activity; but the tendency to indolence is drawn in with every breath of this enervating air.

There seems to be no reason why the American soldiers, if they come to the Philippines, should not be practically free from serious illness, as the bugbear of tropical disease can generally be avoided by a reasonable regard for the laws of health and observation of recognized sanitary precautions. If the American soldiers and marines feel dissatisfied with plain fare, which is the only proper and safe fare in this climate, they should remember that the battle of Cavité was won on a breakfast of hardtack and coffee.

THE MORBIDITY OF THE UNITED STATES FORCES FOR THE FIRST CALENDAR MONTH IN THE FIELD AT TAMPA, FLA.

By HENRY I. RAYMOND, M.D.,
CAPTAIN AND ASSISTANT-SURGEON, UNITED STATES ARMY.

I HAVE thought it would not only be of interest to statistically review the diseases affecting 10,000 regular troops during their first calendar month in the field at Tampa, but also to use this review as a basis of comparison for the morbidity that will be revealed during their first month of foreign invasion or occupation; or, perchance, for comparison with the morbidity of an equal number of volunteer troops.

The mean strength upon which the following statistics are based include 477 officers, 7978 enlisted men (white), and 1666 enlisted men (colored), or a total of 10,121. The number of days lost to the Government from sickness was 5120, or proportionally about one-half a day for each individual soldier included in the mean strength of the command.

There were ten cases of discharge on surgeon's certificate of disability, or one-tenth of one per cent. The causes of discharge were, chiefly, epilepsy, gonorrheal epididymitis, and ulcers from varicose veins, and one case of mild insanity was sent to the Government Insane Asylum at Washington.

Of course, epilepsy and insanity are conditions incompatible with the responsible duties of the soldier, and the other conditions above mentioned impede a soldier's locomotion and paralyze his efficiency, for, as declared by a contemporary of Frederick the Great, and as substantiated by the experience of military commanders since his time, the efficacy of a fighting force depends largely upon the power of marching, or (to paraphrase it) on the strength of the legs. Add to this an adequate lung capacity (in which resides the staying powers of the individual), and we approximate very closely to the physically ideal soldier.

It is due to this weeding out process and to the careful recruitment of the past three years that such a splendid spectacle of physical symmetry and proportion was presented to the eye of the spectator when in brigade maneuvers on Tampa Heights a brigade of more than 2000 men was formed in line of battalions closed in mass.

Out of a numerical strength of 10,121 there were 1294 admissions to sick report during the month, or about one-eighth of the entire force presented itself before the medical officer with diseases sufficiently serious to disable for active duty for a longer or shorter period, averaging for the month, as above stated, the loss of about one-half a day to the Government for each individual included in the mean strength of the command, or about four days for each man admitted to sick report.

Among the cases admitted it must be noted that seventy-four were simple vaccinia, or temporary induration with tenderness at the site of vaccination, inoculation with vaccine lymph being practised to a considerable extent on the troops in the field. The most frequent cause for admission, however, was diarrhea, there being 556 cases of this complaint out of the 1427 cases of disease accounted for in the consolidated report for the month, covering 133 cases remaining from the previous month, and 1294 cases admitted during the current month. Whatever may have been the causes of these diarrheas, and they have been variously attributed to heat, to marked diurnal variations of temperature, to indiscretions of diet or cold drinks when the soldier was overheated, to sleeping upon the ground, etc., it was noted by me that as soon as the men were placed upon the transports these catarrhal conditions of the intestinal canal tended rapidly to disappear, and the opposite condition—one of relative constipation—set in. But, again, the consolidated report shows but six cases of alcoholism during the month. Think of it! But six cases of alcoholism among 10,000 soldiers for thirty days on an active campaign! Can the municipal records of a town of that size in an average community vie with that report? Under my personal observation in Tampa and vicinity during the past six weeks there have come but two or three cases of drunkenness, and no case of beastly intoxication. Beer has been consumed, but only in moderation, and the soldiers have largely resorted to non-alcoholic drinks.

There have been 36 cases of heat exhaustion, but all of them mild, and promptly relieved by the plentiful use of cold water to the head and forearms, and there have been 80 cases of wounds (not gunshot), usually slight, and 77 cases of contusions and sprains, also slight or insignificant, as a rule, together with 30 cases of abscess or localized pus formations, such as otorrhea, whitlows, and the like, and also 27 boils, occurring chiefly in cavalrymen. But 7 cases of typhoid fever are recorded, although among the 33 cases classified as "not diagnosticated," there were doubtless a number of typhoid cases transferred to Divisional Hospitals before the diagnosis had been established. One surgeon reports two cases of gonorrheal ophthalmia, and states that they were undoubtedly innocently contracted owing to concealment and lack of precautions on the part of one or two individuals who were found to suffer from a specific urethral discharge.

An inspection of companies was made in the appearance of the second case, and a thorough investigation of the command in which the disease appeared, together with a word of advice, stopped further infection.

The 1427 cases of disease and injury in the consolidated report are classified under fifty-four headings. Those most frequently encountered, and in the order of their frequency, appear in the following list:

Diarrhea, 556 cases; wounds (not gunshot), 80 cases; contusions and sprains, 77 cases; vaccinia, 74 cases; malarial intermittents, 54 cases; rheumatism, muscular, 48 cases; heat exhaustion, 36 cases; gonorrhea, 34 cases; simple abscess, 30 cases; dyspepsia, acute, 27 cases; boils, 27 cases; skin affections, 25 cases; bronchitis, acute, 25 cases; intestinal colic, 24 cases; chancroids, 19 cases; hemorrhoids, 18 cases; measles, 11 cases; syphilis, 10 cases; gunshot wounds, 5 cases; appendicitis, catarrhal, acute, 1 case.

The daily average sick of the command was only two-tenths of one per cent. No death was reported. These statistics refer only to regular troops, but one report of sick and wounded having been received from volunteer regimental surgeons up to the date of consolidation. It is expected, of course, that the sick of the volunteer commands will figure in subsequent consolidated reports. The troops are now in Cuba, but the vigilance of the sanitary officers of the command cannot be relaxed. During the first night on the transport "Saratoga," to which I was attached, provision had to be made for accommodating as many enlisted men as possible on the cabin decks, while very few were allowed to remain below, where the temperature was over 100° F., and proper ventilation impracticable while the transport was detained at the dock for loading.

Daily cleansing of the decks and policing of the vessel, and thorough and frequent flushing of water-closets, and other sanitary precautions were promptly inaugurated as preventive measures against sickness.

As the "Saratoga" was about to swing from her moorings for a cruise around the bay in search of a breath of fresh sea air, your correspondent was detached from the vessel by a War Department order, directing him to report at Chickamauga National Park, and he had, therefore, to forego the distinction of accompanying the first Army of Invasion upon Cuban soil.

THE ADVANTAGES OF THE CAMP AT CHICKAMAUGA—HARD WORK FOR THE RECRUITS—REMARKABLE HEALTH OF THE TROOPS.

(Special Correspondence of the MEDICAL NEWS.)

Camp Geo. H. Thomas, Chickamauga Park, Ga., Headquarters First Division, First Army Corps, July 3, 1898.

THIS is an ideal place for a camp. It is on a plateau between Lookout Mountain on the west and the Buzzard Roost range on the east, from 600 to 700 feet above sea-level. The soil is clay, non-absorptive, on a limestone formation which crops out in the dips and hollows. The hills are mainly gravel deposits, the moraines clearly showing glacial action. This broad plateau is covered by a growth of oak, hickory, and Southern pine, from which within the park limits the underbrush has been cut. The natural water-supply is from the celebrated Crawfish Spring and Cave-rock Spring, from the former of which a pipe line, six miles long, has been laid which affords all the troops not only with a plentiful supply of cooking and drinking-water, but also is amply adequate for bathing purposes. This is supplemented by driven wells, which are from 60 to 150 feet deep, and piped to bed-rock so as to prevent any surface drainage entering in any way. The climate is warm, 104° F. in a tent not being uncommon temperature, but the extreme dryness of the atmosphere renders it possible to do very much more active labor than one could in New York with the thermometer registering 80° or 90° F., and with the amount of humidity customary in July or August. The dryness of the air here is shown by the fact that after the battle in September, 1863, there being no rain for some time, many of the killed, lost in the underbrush which then covered the battle-field, were afterward found mummified. This great dryness makes the dust very trying, and were it not for the thunder showers which occur frequently, and with almost a tropical downpour, it would be unbearable. The clayey soil is capable of pulverization into an almost impalpable powder, which sifts into every nook and crevice with astonishing rapidity, and the encampment can easily be distinguished from Lookout Mountain by a dense, yellow cloud which obscures it during the day, due

to the feet of marching men and 7000 mules and horses. The thunder showers wash this from the atmosphere, leaving it clear and wonderfully pure.

The first thing that strikes one at this camp is the tremendous grim earnestness of all, both officers and men, and the singleness of purpose animating every one. The material is wonderfully apt and adaptive. Originally clerks, farmers, mechanics, lawyers, doctors (for not a few of our profession are in the ranks), from all callings in life, they are being hammered into shape as soldiers by the hardest sort of drill and training. It is wonderful to see them improve almost daily. By weeks the improvement is as distinct as the steps on the pyramid of Gizeh. The raw Kentucky mountaineer comes in lank, slouchy, and stooping, shambling of gait, careless of his personal appearance, and in many cases barefooted, and anything but soldierly in carriage. A week's setting-up exercises, calesthenics, given an hour every morning and afternoon, the clean uniform that must be kept just so clean, and the daily inspections make a new animal of him—clean, straight, intelligent, and neat.

We have not many sick; the men are getting acclimated, and are learning to care for themselves. Regiments, like the First Maine and the Wisconsin troops, which came with good camp cooks, drawn from the lumber camps, who could properly prepare the rations, have had little or no trouble with their food, but some of the regiments from other States, mainly recruited from small towns, have had much to contend with in this respect.

The very hardest thing for the National guardsman or militiaman to unlearn is the fact that he is no longer in any State organization, and that this is not the summer camp which in days gone by has been a place of pleasant outing, but is *war* and that it means *work*, *work*, *work*, of the very hardest kind. They have first some things to unlearn, and then they must begin to learn, first that in the army the cleanliness that out of the army is next to godliness takes precedence of every thing else by miles. *Clean, clean, clean, be clean!* is the cry of every inspecting officer, and the habit of cleanliness is the hardest thing to teach the National guardsman, for he has always had some one to keep him clean, and he thinks it tough and soldierly (God save the mark!) not to change his undershirt any oftener than possible.

The prevailing disorders have been mainly enteric, and the causes have been threefold: first, the improper preparation of what was really a most excellent ration by bad and inexperienced cooks; second, exposure to cold after the evening meal. This is explained by the fact that the men come in from evening parade, which occurs just after supper and while the day is yet warm, and many of them do not change their underwear which is wet with perspiration, for the suit which they should have worn the day before, and which should be ready and well sundried, but lie down in their wet perspiration-soaked clothes. The nights are quite cool here and the radiation very great, consequently the trooper needs two blankets before daylight, as a rule. The body surface of these men gets chilled, and digestion being stopped, diarrhea follows from fermenting undigested food. The third factor is the "boxes from home," sweets, so-called soft drinks, and cakes and pies, all of which are much more deadly than any Spanish bullet. The improper preparation of food is being remedied by the process of natural selection, while the ills connected with damp clothing by the care of company and medical officers is rapidly disappearing. A stringent order from headquarters absolutely prohibiting the sale of soft drinks, pies, cakes, etc., has recently been issued, and with marked results of improvement.

This, in a way, brings me to speak of regiment canteens. Strange as it may seem to the advocates of total abstinence, the regiments which have a regimental canteen and which regulate the sale of beer to their own troops have also the best sick reports. I may say that there is also absolutely no drunkenness among the troops. This is very strange among such a large body of men, but it is true, and the proof is that there are no prisoners in the guard-tents—not even enough to police the camp sinks and keep them clean for a punishment. The reason for this is that in the intense absorption of the men in their work they have no time for carousal, and in the doing of so much hard work they have weariness at night demanding sleep. Withal, a man intoxicated is a man disgraced with his comrades. The older officers, many of whom served in the War of the Rebellion, remark the improvement in this regard since that time.

The present organization of the Medical Corps is to separate almost entirely the surgeons from the regimental formations and to leave no sick in the regimental hospitals, transferring all to the division hospitals. This leaves but one surgeon with each regiment, all others being transferred to service in the division hospitals and ambulance service, the former receiving all cases from the regiments and the latter making all such transfers. The staff of each division hospital, consisting of a chief and five assistant-surgeons, is so organized as to receive and care for all such cases as would be classed as "in-patients" at one of our hospitals in New York, and those answering morning sick call who would be treated as ambulant or "out-patients" are cared for by the remaining regimental surgeon in their quarters.

The regiments have been vaccinated by half companies at a time and many of the men by reason of infected arms, a double infection in most cases, are for a few days unfit for duty. These, however, are rapidly recovering, the virus used being entirely bovine and of the best quality.

The problem of camp drainage has been the most difficult one in many ways to handle. The proper construction of the sinks and latrines and their proper disinfection and policing being something that even the highest medical authorities were at least inexperienced in arranging and directing, while to the National Guard, line, or field officer they were mysteries unsolved. The recruit himself, in the densest ignorance, thinking that camp sanitation had not improved since the days of Moses, when that great general led his troops out of Egypt, went out of camp and took his spade with him "every man that he might cover what he had done." He soon began to

meet poison oak and ivy, which quickly proved a case taken in *flagrante*. Upon this subject I will soon send the MEDICAL NEWS another letter as I have a design for a latrine which has been accepted by the commanding officers at Camp Thomas, medical as well as military.

The fact is all are learning, and the men here are becoming soldiers in every sense of the word. It was a grand sight to see 10,000 Pennsylvania, Ohio, Wisconsin, Illinois, and Kentucky troops recently leave the field at a swinging double to make room for those following on the day of the division review. Truly these men are getting into magnificent form and every day brings a smaller and smaller sick return, which shows that this camp is a thoroughly healthy place and for instruction and mobilization unequaled.

JOHN MCG. WOODBURY, M.D.,
Major and Acting Chief-Surgeon, 1st Division, 1st Army Corps.

MEDICAL PROGRESS.

Complete Removal of Tubercular Glands of the Neck.—LAPLACE (*Jour. Am. Med. Assn.*, June 4, 1898) advocates the complete removal of tubercular glands of the neck, believing that the sooner such foci of disease are removed the better. The patient can then convalesce and regain health under the influence of general tonic and hygienic treatment. The main contraindication to this method of treatment is the presence of tuberculosis of the lungs, for experience has shown him that the pulmonary involvement will grow with added vigor after the removal of affected cervical glands. Tubercular glands of the neck must be differentiated from Hodgkin's disease, from lymphosarcoma, secondary metastatic lymphoma, and from syphilis. The diagnosis is usually easy. After the removal of the glands patients improve rapidly, and only in exceptional instances is there a fresh development of other glands. If care is taken to make the incision a simple one, and to secure primary union, the resulting disfigurement is slight, far less than follows if the affected glands are allowed to suppurate and discharge.

A New Method to Restore an Asphyxiated Child.—STRINGER (*Vir. Med. Semimonthly*, May 13, 1898) calls attention to the fact that the asphyxiation of an infant after a difficult labor, being due to a lack of oxygen, may be overcome if the blood is kept oxygenerated, until the sensitiveness of the child is sufficiently restored to permit normal breathing to begin. He discovered quite by accident that this oxygenation may go on through the surface of the placenta if the latter is exposed to the air. Having had a miscarriage case at the fifth month, in which the fetus, the membranes, and the placenta all came away together, he wrapped up the specimen with the intention of examining it the following morning. Great was his surprise to find several hours later that there was still a pulsation of the heart. Life had evidently been prolonged by the aeration of the blood, which took place through the placenta. Stringer has since had occasion to test this method in the case of several full-term children born asphyxiated, and has found it to work admirably. As such cases usually follow long and difficult labors, the placenta is already separated in whole or in part, so that its removal does not present any difficulty. It is to be removed as soon as possible, its surface washed and exposed to the air, when the child will live an indefinite time, as it did in the uterus, without respiration. When respiration begins, which was not for twenty-five minutes in some of the cases, pulsation in the cord will cease, and it may be tied and cut.

Diphtheria of the Vulva.—COUES (*Bost. Med. and Surg. Jour.*, May 12, 1898) reports two cases of diphtheria of the vulva occurring in children less than two years of age, the diagnosis being confirmed by bacteriologic examination. In one of these cases the affection of the vulva was secondary to the same trouble in the throat, and the patient died. In the other the lesion was primary, and the patient recovered. This makes three cases of diphtheria of the vulva which Coues has seen in less than a year, so that the trouble is probably not very rare. He advocates the examination of the genitals of every female child who contracts diphtheria in its throat.

THERAPEUTIC NOTES.

Metrorrhagia of Puberty and Its Treatment.—ROMME (*La Presse Med.*, May 4, 1898) says that the metrorrhagia of puberty is a particular type of this trouble, and is due to a debilitated state of the system from tuberculosis, rheumatism, or some other disease, the uterus, however, being in an essentially normal condition. The metrorrhagia usually follows the first attempts at menstruation, and the flow of blood is either constant, or if it ceases when the patient is absolutely quiet, recurs upon the least effort. Examination yields negative results. Hydrotherapy, with massage and friction of the whole body with rough gloves, gives satisfactory results. Sea-bathing is a powerful restorative, but must be commenced with great caution. An out-of-door life and moderate exercise, with a bicycle or in some other way, supplemented by such tonic and laxative medicines as may be called for, generally effect a cure. There is little help to be expected from local treatment, though a weak antiseptic douche may be used to prevent infection in the upper genital tract. Curettage is rarely indicated. For hemorrhage which threatens immediate danger the patient should be kept on her back and ice applied to the abdomen, or hot vaginal douches be given.

The Acne of Young Girls and Its Treatment.—BROCQ (*Rev. de Therap.*, May 15, 1898) says that most girls who are troubled with acne of the face are continually rubbing and scratching it, not so much on account of any feeling of itching as because of an irresistible impulse to do so, which may well be compared to a mania. Hence the importance of requiring them to wash their fingers and brush their nails many times daily with a solution of boracic acid in order to avoid infection. Treatment should accomplish the following ends:

1. The overcoming of the coldness of the lower extremities by daily friction with cologne, spirits of camphor, or by flagellations with cold water.

2. The cure of any uterine difficulty.

3. The relief of habitual constipation, by the administration to the bilious of cholagogues, and to those with a flushed countenance of preparations of aloes. The latter should never be given to patients who have hemorrhoids or genito-urinary troubles.

4. The regulation of the diet. Small meals with little fluid at a time, and plenty of out-of-door walking should be the rule.

5. The avoidance of stiff corsets and stiff collars.

Alcoholic drinks, pork, fish, cheese, shell-fish, and pastry should be prohibited. The remedies which are of most value are the laxatives, especially magnesia and washed sulphur; the alkalies, intestinal antiseptics and betanaphthol. Sometimes arsenic, sulphid of calcium, chlorid of sodium, ichthyol, nux vomica, and carbolic acid are of service. Brocq has had good success with brewer's yeast, of which half a teaspoonful or more is taken in water with each meal. If brewer's yeast is not obtaintable, baker's yeast may be substituted.

These patients should never wash with sponges, but only with swabs of absorbent cotten, wet with a hot solution of borax and soda—two teaspoonfuls of boracic acid, and one each of borax and bicarbonate of soda to a quart of water. If there is much seborrhea, a little tar soap or compound tincture of benzoin may be added. At night the face should be washed with a naphthol soap, for which may be substituted once or twice a week the following mixture:

℞	Resorcin	ʒ j
	Ac. salicyl.	℥ j
	Sap. virid.	ʒ iij.

After the soap has been used the patient puts on each pustule a small amount of a pomade, prepared as follows:

℞	Resorcin		gr. j
	Betanaphthol, Camphor	aa	gr. xiiss
	Cret. preparat.		gr. xv
	Sapon. nigris		gr. xxx
	Sulph. precip.		gr. c
	Lanolin, Vaselin	aa	ʒ j.

The next morning the patient washes the face with spirits of camphor, and if she has to go out, applies a little of the following:

℞	Acid salicyl.	gr. xv
	Zinci oxid.	ʒ iij
	Lanolin	ʒ vj
	Vaselin	ʒ xij.

The face is then gently wiped and dusted with starch powder.

The Best Way to Rub in Mercury.—UNNA (*Rev. de Therap.*, May 15, 1898) says that mercurial inunctions are better made with a soap (*sapo cinereus*) than with the classical gray ointment. The soap is prepared from lard and potash-lye, to which is added five per cent. of benzoinated lard and one-third of its weight of mercury. In its therapeutic action 4 drams of this soap will equal 6 drams of gray ointment. The soap is rubbed in with the hand, which should be moistened with warm water four or five times during the fifteen minutes which are necessary to insure a thorough penetration of the mercury. There remains on the skin only a thin, grayish film. This method has several advantages. It is far more cleanly than the application of the ointment, the mercury is more quickly absorbed, while it is applicable to very greasy skins, which resist the ointment. Soaps may also be made of the salts of zinc, lead, etc., for the treatment of obstinate skin diseases, acne, lichen, etc.

Lavage in Gastro-Intestinal Affections of Infants.—EPSTEIN (*Rev. de Therap.*, May 15, 1898) has practised lavage in infants more than 2000 times, and has never seen the smallest accident result therefrom. A small glass funnel and a rubber tube 40 to 45 centimeters in length and 6 millimeters in diameter are all the apparatus required. It is necessary to introduce the tube to a depth of 23 to 30 centimeters (10 to 12 inches) in order to reach the stomach contents. As soon as the tube comes into contact with the walls of the stomach they contract and force out fluids, and if the organ is dilated usually a quantity of gas comes out also. Warm water, to which 3 parts of salt per 1000 have been added is used to wash out the stomach, not more than an ounce being poured in at a time. This quantity is introduced and withdrawn several times. Cyanosis may be produced by the introduction of the tube, but it is not dangerous in any way.

The lavage is contraindicated in collapse, and also in the presence of cardiac and respiratory lesions. It finds its chief use in acute gastro-enteritis in order to rid the stomach of the products of fermentation, to which are due the grave symptoms of this disease. But it should not be forgotten that the stomach of a healthy infant is empty one and one-half hours after nursing, so that if it is found to contain fluid three or four hours after nourishment has been taken, it is in a pathologic state. Lavage, therefore, can also be of service in chronic dyspepsia, as well as in the more acute forms of this disease.

Treatment of Somnambulism.—HIRSCHKRON (*Ther. Monatsh.*, May, 1898) says that somnambulism is an imperfect sleep, in which the motor areas are disturbed by dreams. While sleep-walking occurs frequently in individuals of a hysterical type, the treatment usually applied for such conditions fails of its purpose in somnambulism. He had good results, however, following the application transversely through the medulla of a galvanic current of electricity. Eight or ten sittings were sufficient to cure an obstinate case of sleep-walking, and a recurrence which took place some six months later was banished by a single application of the current. The galvanization of the medulla probably acts by strengthening the vasomotor centers, so that the flow of blood to all parts of the brain is abundant and the anemic condition of part of the brain which is responsible for the nightly excursions of the patient is done away with.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE $4.00
SINGLE COPIES 10

SATURDAY, JULY 9, 1898.

THE SPANISH BULLETS.

THE terrific execution done by the Spanish bullets among our troops in Cuba, and which at first led to a severe arraignment of the Spaniards on the supposition that they had mutilated the dead, is explained by the fact that they used rifles of small caliber, but affording great initial velocity to the projectile. The Mauser rifle used by the Spanish army, and the Krag-Jorgensen with which our regular troops are equipped, are weapons of this character. It was to be expected that the wounds inflicted upon the Spaniards by our troops would be of the same description as those sustained by our men. A careful examination of the Spaniards kil'ed in the various engagements confirms these expectations, and therefore refuted the charge of mutilation.

The missiles from these weapons work their worst havoc at the point of exit. The wound of entrance, wherever it may be, regardless of the varying density of the different tissues of the body, is usually no larger than the size of the bullet, while the orifice of exit is large and jagged. Whatever theory may be accepted as the explanation of this fact, the effect is beyond question. The careful observations of Dr. Orlando Ducker are of value in this connection. His investigations were made at Camp McCalla, where he had the opportunity of observing the dead of both parties to the conflict. A typical illustration of what he found is presented in the description of the wound in the head of one of the regular Spanish soldiers. The ball entered the frontal bone two inches anterior to the right parietal suture, and two and one-half inches above the temporal articulation, traversed the brain longitudinally, and passed out through the right occipital bone midway between the mastoid process and the occipital protruberance. The wound of entrance, as far as the inner table of the skull was involved, was clean cut and the size of the bullet, although from the outer table a piece was chipped off at the lower margin of the orifice. The wound of exit was irregular in shape, and measured about one inch in diameter, damaging alike the inner and outer tables of the skull. There was a complete longitudinal fracture through the frontal bone. In this case, as in a similar one described, the fracture did not communicate with the wound of entrance or that of exit. These fractures are supposed to have been due to the great velocity of the missile through the brain substance by which sufficient time was not allowed for cell compression, resulting in the bursting of the skull, so to speak. This effect is intensified by a deforming bullet or by an expanding bullet, as it widens the area of compression. An exploding bullet would be still more destructive, but there is no evidence that such a missile is being used by the Spanish forces.

A recent investigation of some samples of Mauser cartridges used by the Spanish troops which were sent to Washington by the marines at Guantanamo, has aroused the indignation of ordnance experts. The bullets were found to be enclosed in brass casings, which, as is well known, can hardly fail to cause blood-poisoning in a person wounded by them, no matter how slight the injury. The use of brass casings is considered nothing short of barbarous, and is not countenanced in warfare by civilized nations.

MALARIA IN THE TROPICS AND ITS PREVENTION.

THE diseases incident to the campaigns in Cuba and the Philippines that are held most in dread even by the medical profession are yellow fever and dys-

entery. The fact that malaria causes more deaths than both of these, except in seasons of unusual epidemics, is often lost sight of. Accustomed to the mild attacks of malaria in their native country, which is looked upon as a distressing illness not particularly associated with danger, it is forgotten that tropical malaria is in the vast majority of cases (from seventy-five to ninety per cent.) an entirely different disease in its manifestations and termination. Even though subject to the most orthodox treatment, it is one of the most fatal of the infectious diseases.

The lesson to be learned from this is that the mortality of our troops in the present war must be kept down by adopting measures that will serve to prevent infection. But prophylactic measures can only be effectual when based upon accurate knowledge of how the infection gains access to the system. The recent investigations of Koch in the German Colonies of East Africa tend to show that the conveyance of the disease by the atmosphere or by water is quite improbable, while, on the other hand, the fact that the disease can be communicated by suctorial insects, particularly by the mosquito, he believes has been established beyond peradventure.

This belief is gradually gaining adherents among our best experimenters and observers, and the investigations of Mason, of Ross, and of others, as well as the corroborative testimony of those who have great personal experience in the Oriental tropics, tend to make this teaching worthy of acceptation.

It is a fact that malaria affects those who engage in breaking up the soil; those who sleep on or near the earth; those who bathe in and drink stagnant, marshy water; those who are fatigued by long marches and enervating surroundings; but it would seem to be becoming yearly more evident that these are merely contributory causes of a kind that may be operative to facilitate the occurrence of any infectious disease. The fact that none of the plasmodia of malaria has yet been found in any other human media than the blood is a very strong argument in favor of the view which attributes the spread of malaria to the propagation of blood parasites by the mosquitoes.

It will be seen from reading our Berlin letter of this week that Koch considers the use of the mosquito net the most efficient means of preventing malarial infection. He, like other investigators and travelers in infected countries, was able to completely ward off the disease by the employment of this comparatively simple expedient. This, taken in connection with the statements of Emil Pasha and other travelers concerning the efficaciousness of mosquito-netting, tends to increase our faith in it as a part of the soldier's outfit. It may be possible to provide our troops with mosquito netting and hammocks made of some extremely light material. Then, if discipline is enforced with sufficient rigor to prevent soldiers from bathing in marshy, stagnant water, where mosquitoes find their greatest facility in propagating, in becoming the extra corporeal host of the plasmodium, and in carrying their poison into the human body, our campaign in Cuba may be robbed of what verily seems to be now one of its greatest terrors.

Another very important fact that should not be lost sight of is that most investigators of the etiology of malarial fevers are united in the conviction that quinin is the most reliable prophylactic agent, although it is often given in too large doses. Koch avers that "black-water fever" is nothing less than hematuria due to the toxic effect of quinin, plus malarial fever. There is no doubt that the plasmodia are extremely susceptible to the action of quinin, even when given in small quantities. Our soldiers should profit by the experiences of the French troops in Madagascar and of the Germans in their East African possessions in warding off malaria. It was the unanimous sentiment of those who studied the medical side of these campaigns that quinin, 6 to 10 grains in twenty-four hours, was a most efficient prophylactic, provided reckless and unnecessary exposure was avoided. The most reliable preparation is the hydrochlorate, and the most suitable way of administering it is in capsule or tablet form at meal time.

Dr. Hyatt, the United States Consul formerly at Santiago de Cuba, in a recent personal interview, stated that during his two years of residence there his only means of avoiding malaria was by the constant administration of quinin. By taking about 4 grains of the sulphate of quinin uninterruptedly every day during the past year, every member of his family had escaped without an unpleasant symptom. The least remission in this custom, however, was attended by immediate warnings. This is the testi-

mony of a physician who had not only studied the local climatic and sanitary conditions for a year, but had endeavored to avoid as far as possible the taking of drugs. It must be borne in mind, too, that he was living under the best hygienic conditions, and amid the best sanitary surroundings that could be obtained. For a soldier undergoing all the hardships and exposure of a vigorous campaign in that country, 6 or even 8 grains of quinin daily would probably be required to produce immunity. But every dictate of prudence and of wisdom demands that he should have this security against so pernicious a disease. The exigencies of the campaign may make it impracticable to institute the universal employment of mosquito-netting, but quinin can be readily served with the soldiers' rations. In the light, therefore, of what is now known upon this subject, every soldier who loses his life from this malignant disease will be recorded as a needless sacrifice at the hands of the medical arm of the service, and every combatant who returns with his constitution wrecked by tropical malaria will justly hold the same officers responsible.

Quinin is procurable at the present time in almost any quantity. There would seem to be no reason why there need be any delay in promptly carrying into execution this imperative demand.

ECHOES AND NEWS.

Medical Men in the French Parliament.—Among the members of the recently elected French Parliament are forty-seven medical men, five chemists, and one veterinary surgeon.

Dr. Wiggin's Appointment.—The Commissioners of Public Charities recently appointed Frederick Holme Wiggins, M.D., of New York city, assistant visiting surgeon to Bellevue Hospital.

Local Analgesia.—Hackenbruch, who recently read a paper on this subject before the Surgical Congress at Berlin, considers the term more correct than that of local anesthesia, which is generally employed.

Yellow Fever in Mississippi.—During the week ending July 2d only two cases of yellow fever developed in Mississippi and in these patients the source of contagion was easily traced. Their isolation has been perfect. Passed Assistant Surgeon Giddings maintains a small detention camp at McHenry.

Railway Hygiene in Austria.—The medical officers of the Austrian railways have requested the Government to have posted in each compartment a notice to the effect that spitting on the floor of the railway carriages is forbidden. The third-class carriages are washed at stated intervals with a five-per-cent. solution of carbolic acid.

Chicago Society of Internal Medicine.—A medical society with the above title has recently been organized in Chicago. It is announced that the chartered members will be limited to gentlemen of reputation in internal medicine, the future admissions to be approved by theses, the object being to lay the foundation for a society of the highest order of scientific excellence.

The X-Ray in Ophthalmic Practice.—The latest use to which the Röntgen-ray has been put is in ophthalmic practice, in which it has recently been employed in London to locate a piece of metal lodged in the ciliary region of the eye of a child. The skiagraph plainly showed the bit of metal, which was removed by an electromagnet after an incision had been made.

Protection of British Troops by Means of the Medical Supervision of Women.—A memorial signed by upward of 1000 mothers in various parts of the country has been forwarded by the Countess of Carlisle to Lord Salisbury, protesting against the principle involved in protecting the health of British troops by the system of medical supervision of women in the cantonments.

Foundlings in Moscow.—At the Imperial Foundling Home of Moscow, which receives annually more than 17,000 abandoned infants, the babies are dressed in swaddling clothes and their arms bound down to their sides during the time they are under the care of the wet-nurse. The latter sleeps on a straw mattress that lies upon the floor in front of the baby's crib, which is of metal.

Necessity Makes Queer Bedfellows.—One of the most distinguished medical men and scientists in the Russian Empire is about to visit England on an important mission. The extension of the Russian Empire in Asia has increased the necessity of taking measures for combating infectious diseases. Dr. Dembo has been instructed, therefore, by the imperial authorities to visit western Europe, and consult with British authorities as to the means adopted in their far-off possession for checking disease.

New Hot-water Bottles.—The expensiveness and want of durability in the ordinary rubber bottles and ice bags which have become so essential in the sick chamber, has long been a perplexing problem. Experiments with rice paper covered inside and out with a coating of Japanese lacquer led Professor Jacobsohn to recommend this material to the Berlin Society of Internal Medicine as far superior to rubber. In strength, flexibility, imperviousness, lightness, and durability it leaves little to be desired.

Hamlet a Neurasthenic.—According to Dr. T. W. Hime of Bradford, Eng., Hamlet was a victim of neurasthenia. In a communication presented to the Sheffield Literary and Philosophical Society, he says "Hamlet was a marvelously true representation of a person suffering from a

state of instability of the nervous system and of all the neurotic states dependent upon it. Hence he became a characteristic victim of neurasthenia, ready to burst out into vehement declarations of his irresistible determinations, but incapable of converting them into action."

Gratitude Galore.—According to the *Medical Press and Circular* the following death notice recently appeared in an English newspaper: "Smit.—On the 28th inst., Amy Jane Mary Smit, aged one day and two and one-half hours. The bereaved and heartbroken parents beg to tender their hearty thanks to Dr. Fealton for his unremitting attention during the illness of deceased, and for the moderate brevity of his bill; also, to Mrs. Williams for the loan of clean sheets, to Mrs. Jurgens for running to the doctor, and to Mr. Le Roux for recommending mustard plasters."

Plague in Hong Kong.—Two nursing sisters have died from the plague in Hong Kong. A plague patient in delirium coughed in the face of Miss Elizabeth Frances Higgin (Sister Frances) on April 20th; on the 25th she became ill, and was found suffering from bubonic plague, the worst form of the disease. She died on April 29th. The sister who attended her, Miss Emma Gertrude Ireland (Sister Gertrude), was admitted to the hospital May 2d. The next morning the typical bacilli were found; she died May 5th. Both these sisters served through the plague epidemic of 1894.

Honor to Whom Honor Is Due.—Under this caption the *British Medical Journal* points out the fact that Professor Koch in his recent address on malaria does not claim to be the discoverer of the facts narrated by him, *viz.*, that the cattle tick is the means of transmitting Texas fever from one creature to another, that Texas cattle fever is produced by a germ, and that the mosquito is a propagator of malaria. M. Lavaran is the discoverer of the malaria parasite and Dr. Manson distinctly indicated the *rôle* of the mosquito in malaria, while Surgeon-Major Ross demonstrated the presence of the malarial parasite in the tissues of the mosquito.

Sanitation as an Investment.—In the United States alone the loss through typhoid fever and other water-borne diseases is beyond ordinary comprehension. It is not far wrong to estimate the number of persons annually thus afflicted at 300,000, of whom 50,000 die. At the lowest legal valuation set upon human life the enormous total of $278,000,000 is found to be the equivalent cash loss. If by improvement of the water-supplies the death-rate could be reduced eighty-five per cent. $236,000,000 would remain for this purpose and this amount at five per cent. annually for interest and sinking-fund charges for forty years would justify an outlay of no less than $4,054,671,000 for water purification.

Typhoid Fever at Camp Alger.—A number of cases of typhoid fever have developed at Camp Alger and a commission has been appointed to examine the water-supply. That a question so important in the selection of a camp should have been deferred until after occupation seems almost incredible. Since a large quota of the victims were furnished by the New York Cavalry it is not impossible that the germs of the disease were acquired before the men reached Virginia. It is a notable fact, however, that in the instance of a Pennsylvania regiment whose officers had the forethought to order a sufficient supply of Poland water, the perfect health thereby maintained has more than repaid for the trouble and outlay.

Physiological Chemistry at Columbia University. — The College of Physicians and Surgeons, New York, is to have the advantage of an improved curriculum in this subject. The second-year men will receive a systematic drill therein, both by lectures and by practical work in the laboratory under most favorable auspices. Professor Russell H. Chittenden of the Sheffield Scientific School, who has won for Yale so high a standing in practical teaching and in research work in physiological chemistry, and for himself a commanding position as an instructor and investigator, is, without relinquishing his duties at New Haven, to direct the organization and conduct of the new department here, and to give weekly lectures. William J. Gies, Ph.D., has been appointed Instructor in Physiological Chemistry; Alfred N. Richards, A.B., and Henry E. McDermott, A.B., assistants.

Experimenting with Bacteria.—Transferring bacteria by subsurface has been made by several experiments in clearing the forests near the Rhine. Two pits were used as the tests. One pit was 3.3 feet deep, and in the ground the water rose to about 1 6 feet from the surface. The other pit was 24 feet distant in a line perpendicular to the direction of the flow of the subsurface water. This second pit was 4.9 feet deep, 3.3 feet wide, and 39 feet long. Two specimens of bacteria were selected, micrococcus prodigiosus and the fluorescent vibrio. These are not found in the Rhine. The cultures of these species were placed in the first pit, and at intervals of half an hour samples were taken from the second pit and cultivated in the usual way on gelatine or agar plates. It was discovered that in an hour the micrococci and in two hours the vibrios had passed through the 24 feet of gravel separating the pits.

Will Another Johns Hopkins Arise?—What is needed just now in London to promote the cause of post-graduate instruction is a liberally devised and munificently endowed hospital and college. There is a post-graduate system in that city, but it differs from our American models in that it lacks centralization; it is obliged, so to speak, to go "boarding 'round" at widely separated small special infirmaries. The *Lancet* announces the fact that a new departure has been brought to its notice, namely, "a scheme for the foundation of a Medical Graduates' College and Hospital on the American rather than the Continental plan—that is to say, a college and hospital where qualified men alone are to be taught. We recognize the difficulties which must attend any attempt to combine teaching for students with post-graduate instruction. Of course, a college and hospital for post-graduates alone would be a more desirable method for giving the special

instruction they desire, but in order to do this with efficiency provision must be made on a large scale. Lecture theaters, class-rooms, laboratories, a museum, and a library must have places in such a college, and such a hospital must attract by the wealth of its general and special clinical material and by the reputation of its teachers. Public consultations and advice to medical men on the diagnosis and treatment of their cases will require very careful management or they may possibly come to be regarded in a false light. It is hardly likely, therefore, that the scheme will receive much support from the teachers and governors of our general and principal special hospitals and in many instances an active opposition may be excited. The medical profession may subscribe liberally to the foundation and endowment of such an institution, but as the patients will not be admitted into the hospital for prolonged treatment, but rather for the purposes of teaching, it is questionable whether it will derive much support from the general public. If another Johns Hopkins can be found to provide the necessary funds the scheme will be carried out easily, but unless some munificent benefactor arises we are doubtful whether the project, which has much to recommend it, can be brought to a successful issue."

CORRESPONDENCE.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

KOCH'S OBSERVATIONS IN SOUTH AFRICA CONFIRM PROFESSOR SMITH'S DISCOVERIES IN CONNECTION WITH TEXAS FEVER—TROPICAL MALARIA—MALARIAL HEMATURIA AND QUININ POISONING—THE ROLE OF THE MOSQUITO—IMMUNIZATION AND SERUM-THERAPY.

BERLIN, June 25, 1898.

PROFESSOR KOCH has been the recipient of a series of most flattering attentions since his return from South Africa. He was met by a party of friends the evening of his arrival in Berlin, was given a banquet during the week, and on Thursday evening, on the invitation of the Deutsche Colonial Gesellshaft of Berlin, gave an account of his medical observations before an audience, assembled by invitation, that included many of the medical notabilities of Germany. Prince Arenberg, the president of the Colonial Society, presided.

Practically the whole of his talk was devoted to the subject of malaria. It had a special appropriateness to the occasion, since it is the existence of malaria in German East Africa that makes the work of colonization so difficult. The subject of Texas fever was also introduced because Koch has found it in East Africa, and it has in its etiology certain probable analogies with malaria which make it interesting. The Texas fever of East Africa Koch does not consider an importation from America. He has been able to ascertain by careful questioning of the older inhabitants that the disease in practically its present symptomatic form has existed there for generations. In fact, there is no tradition going back to its first appearance, so that it may be considered to have been endemic for 100 years at least. Koch took the occasion thus afforded him to repeat some of Professor Smith's experiments. He had not the time to repeat all of them, but was able to substantiate the extremely interesting observations as to the parasite of the disease, the intracellular pirosoma bigeminum, and its host a parasite of the tick family that infests cattle.

The communication of the disease by the ticks to the cattle was the subject of special study, particularly the hereditary form of the disease in the ticks, or at least the possibility for insects of this kind that had never been on animals affected with the fever, nevertheless communicating the disease to cattle. Koch raised several generations of ticks, and then having carried the young to a part of the country where Texas fever was unknown, placed them on healthy animals. Twenty-two days elapsed before any symptoms were noted, and he had about given up hope of any result from his experiments, when the report reached him. He expressed hearty appreciation of the acute scientific observation and patient investigation of the American pathologist, and his words were welcomed with marked signs of approval.

Malaria in its tropical forms occupied the rest of the evening. He has found that only about ten per cent. of the malaria that occurs in the tropics is at all like ordinary malaria. The quotidian and tertian forms do occur in about the proportion mentioned, but besides these there are two other forms distinctly tropical. At the height of the paroxysm in tropical fever, there is a persistence of the highest febrile temperature for some thirty-six hours in marked distinction to the almost immediate fall of the temperature after it has reached its acme, as is always seen in America and Europe. The parasite of the tropical forms is very similar to that of tertain fever, but the plasmodium is smaller in the various stages. The so-called spore forms, which are really fully-formed, minute plasmodia, set free after the breaking up of the rosette forms, are not more than one-third the size of the hematozoic sporulation (?) forms of Italian observers. Partly, perhaps, because of their extremely small size, Koch has never seen them in the blood, but has seen them in the spleen.

The constancy with which certain forms of the parasite occur at certain stages of the disease is remarkable. An examination of a blood specimen, though the patient had never been seen, enabled one to say positively in what stage of the disease he was when the blood was withdrawn. There is especially noticeable a small signet-ring form of tertian fever, and having even more distinctly the crescentic enlargement of the ring opposite the signet. In the tropics this is not more than one-half as large as the tertian signet-ring form, and is always found just after the paroxysm is over.

When quinin is given while the parasite is young and delicate, during what used to be called sporulation, though falsely, the plasmodium being less, not more resistant to external influences at this time, it is not hard to break the disease up. Entirely too much quinin is given in the tropics, however, and without due regard to its specific action, which is not any theoretic antiperiodicity, but is

its fatal effect on the plasmodium. One gram (15½ grains) is enough for prophylaxis, and scarcely more is needed to avert a paroxysm during the course of the disease if it is given while the parasites are especially irresistent to its action.

Koch thinks that the *Schwarzwasser fieber* (the black water fever), that is so much dreaded in the topics, the malarial hematuria of the books is really not due to malaria at all, but is a symptom of quinin intoxication. He has never seen it in cases where quinin had not been used, and as an idiosyncrasy for quinin often exists, it is possible for severe toxic symptoms to occur without much of the drug having been taken. Koch has not seen in his tropical experience the remittent form of malaria, and thinks that when there is a febrile temperature between the regular paroxysms of the disease that it is due to some complication.

As to the conveyance of the disease, air and water as media of the contagion being absolutely excluded, Koch thinks that the disease is spread by mosquitos. It exists only where mosquitos are present. Though very common in the islands along the African coast, there is one of the islands off the German East African coast that is free from it, and mosquitoes are not found on the island. Koch found mosquito nets afforded effectual protection against the disease when wandering over infected belts of territory. The analogies for such a means of contagion are by no means wanting. The filaria sanguinis hominis has the mosquito for an intermediate host, without a doubt. The cachexia, fatal in most animals, and often extremely severe in human beings, that follows the bite of the Tsetze fly, is probably due to the inoculation of some organic infectious material capable of reproduction in the organism, rather than to the injection of simple toxic substances. The study of Texas fever is especially interesting in this regard, as showing the possibility of the power of infection being transmitted from generation to generation in the host. It is possible that the cycle of evolution of the malarial parasite in the mosquito may require several generations for its completion. A direct inoculation from person to person by the mosquito seems improbable. As to the therapy of the disease, quinin is effective, yet malaria has always remained the great enemy of colonization projects in tropical countries. The methods usually suggested for ridding a country of malaria are impracticable or ineffectual. The draining of the swamps would be an immense labor and involve huge expense. The planting of eucalyptus trees is humbug. A method of immunization to the disease would open up the tropics to European civilization.

That such a thing is possible Koch firmly believes. Malaria even untreated is in any single attack a self-limited disease, and successive attacks are milder and milder. The negroes on the African coast have an acquired immunity, and have only rare, and then slight, attacks of the fever. Those who live on the mountains inland know that when they go down to the coast they will almost inevitably acquire the fever, but that the risk is less on successive expeditions and the fever ever lighter.

Even our present imperfect knowledge of the parasite may be sufficient to enable us to find a method of immunization. Koch had not been able to demonstrate the parasitic cause of rinderpest, but a practical procedure to secure immunity he thinks he has found. Of rabies almost nothing is known as to its etiology, yet a successful biologic therapeutic method for its treatment has been discovered. The aim of future studies will be in this line, for the object aimed at is one of the most humane, and at the same time utilitarian at present open to scientific study, for the opening up of the tropics will follow the discovery.

The scientific and commercial value of successful investigation here would be far beyond anything that Polar exploration (a German North Polar expedition has just sailed) can promise. Government and colonial interest in the matter must be aroused, and every incentive offered to the pursuance of successful investigation in this line.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

AN INCREASE IN GASTRO-INTESTINAL DISORDERS—THE CITY'S POOR—SUMMER CLINICS AND LABORATORY COURSES—A NEW DIPLOMA MILL?—WATER FAMINE IN GERMANTOWN—THE DRUG-STORE PHYSICIAN—A CHURCH CELLAR AS A BURIAL-GROUND.

PHILADELPHIA, July 6, 1898.

WITH the advent of the intensely hot weather of the past few days and the excessive humidity which accompanied the heat, the dispensaries have been crowded and the number of children suffering from gastro-intestinal disorders has been unprecedented. Heat prostrations, too, have been numerous enough to crowd the facilities of the hospitals and at the German and Pennsylvania Hospitals it is proposed to erect tents for the treatment of this class of patients. Playgrounds have been arranged in various parts of the city, and these, with the numerous small parks which have been made during the past year, it is hoped will mitigate the suffering caused by such intolerable weather. Philadelphia is to be commended for the many improvements which have lately been made in this respect, and together with the improvements soon to be made, in the establishment of more free baths, the condition of the poor in this city will be greatly ameliorated.

While many of the regular clinics are closed, perhaps better facilities for clinical study exist now than are afforded during the winter, for in the absence of many of the older men and in the less crowded clinics there is a chance for every man to do original work and to study cases individually. This is true, also, of the many laboratory courses held by the colleges during the spring and summer, and it is becoming recognized that the student unhampered by other studies and the thought of impending examinations accomplishes more work, and work which is more valuable than the regular instruction of the college term.

With the classes which graduated this spring the reign of the three-year course of instruction ends in this city. The three-year classes graduated by the Medico-Chirurgical and the Women's Medical College are the last, both colleges having adopted a four-year course some time ago,

which had been done by the Medical Department of the University of Pennsylvania and Jefferson Medical College.

After the graduation examinations this spring a student from one of the medical schools who had failed to receive his diploma went to the Baltimore Medical College; after his arrival he wrote to his companions in misery that upon payment of a small fee they could secure diplomas July 1st. Upon receipt of this news a number of students left the city for Baltimore, and at last accounts expect confidently to secure the much-coveted degree. It now remains to be seen what action will be taken by the Pennsylvania State Board of Medical Examiners when these made-to-order physicians apply for a license to practise, a physician of Connecticut, who is conversant with the facts, having stated that they need not apply for registration in his State, as they will meet with a decided refusal.

Possibly the "war scare" may have kept more than the usual number of Philadephians in town, but whatever the cause, there is no doubt as to the number of physicians remaining in the city, whether from a desire to care for these patients or from inability to go away for other reasons. Among those who have gone to Bar Harbor are Drs. Henry C. Chapman and J. Madison Taylor, while Dr. Joseph Leidy is again at Narragansett Pier. Dr. L. Webster Fox is at Spring Lake, N. J., and Dr. Edward P. Davis at Marion, Mass.

Dr. M. O'Hara, Jr., has received an appointment as assistant surgeon to the 20th Regiment of this State.

Dr. Henry Beates has gone to the Delaware Water Gap for a short stay pending the report of the State Medical Examining Board, of which he is a member.

There is a water famine in Germantown which threatens to cause serious trouble. Complaints have been made that the residents of Chestnut Hill and Germantown are unable to get an adequate supply, and in some sections there is absolutely no water except in the early morning. The reservoir at this point is almost empty and the pumps are not sufficient to keep up with the demand, let alone fill the reservoir. It is particularly unfortunate at this time of the year, and only serves to again illustrate the absolute imbecility of the municipality which the people by popular vote empowered to create a large loan for the betterment of the public service in this as in other respects.

Dr. M. F. Middleton has been elected President of the Camden Board of Health. The reports for this year show 615 cases of contagious diseases against 466 for the year before. The last three weeks show an increase of fifty per cent. in the number of cases of typhoid fever.

The Philadelphia County Medical Society is in danger of having no report of its transactions for the past year. When the *Medical and Surgical Reporter* failed last winter the Society had placed these records in the hands of a printer; but as the County Medical Society owed the *Reporter* a small sum of money and the *Reporter* owed the printer a large sum, the latter demands payment of the large sum by the Society as compensation for the reports. The amount has not been paid, and so matters rest for the present.

An interesting question of medical ethics has just arisen in one of the hospitals of this city. A Resident of last year having opened a drug-store in connection with his practice, some of the attending physicians have refused to sign his diploma of residency, while one is urging his confrères to sign, much to the bewilderment of all who know of the affair.

The sexton of Mt. Zion Christian Church has been arrested charged with violating the regulations of the Board of Health. Charles Kennedy, an inspector, testified to finding bodies of children buried in the church cellar but eighteen inches under ground, while one, that of a child who had recently died of diphtheria, was buried at a depth of but two feet. As the law requires that all bodies shall be buried at a minimum depth of eight feet, and this seems little enough, comment is unnecessary.

RUPTURE OF THE BICEPS TENDON.

To the Editor of the MEDICAL NEWS.

DEAR SIR: The following case is, I think, somewhat unusual. Mr. J. W. K., aged seventy-five years fat and of gouty habit, while attempting to throw a stone, fell laterally and struck on his right shoulder. He immediately experienced sharp pain in the shoulder and was unable to raise the arm. When I saw him I made a diagnosis of rupture of the tendon of the biceps muscle at the point of its insertion in the bicipital groove of the humerus. There was more or less settling of the muscle toward the elbow, it failed to contract on flexing the arm, and at the point of rupture there was marked tenderness. The accident occurred during the latter part of August, 1897. The muscle is now very soft and flabby and its contour differs very materially from that of the right arm, although the patient is right-handed. Treatment has failed to improve the condition. Very truly yours,

J. T. BUCHANAN, M.D.

BENHUR, LIMESTONE CO., TEXAS, July 1, 1898.

TEST FOR IMPEY'S THEORY AS TO THE IMMUNITY IN ANESTHETIC LEPERS OF ALL TISSUES EXCEPT NERVOUS.

To the Editor of the MEDICAL NEWS.

DEAR SIR: I recently proposed to Dr. Alvarez, Superintendent of the Leper Hospital, Honolulu, the following experiments which he promised to try:

1. That serum of a blister on an anesthetic leper be inoculated on a tubercular leper to see if any regression of tuberculation results. If there is immunity of all tissues except nervous, I should expect such regression.

2. Take serum from a tubercular leper and inoculate an anesthetic leper. If tuberculation results there is no Impey immunity.

3. Take the serum from an anesthetic leper whose disease has run out and find if it is a remedy for leprosy. It should be if Carrasquilla's theory is right, although the horse has not been subject to the disease for more than a few days and the anesthetic leper has been subject to the disease for several years. But it must be borne in mind that the horse is refractory and the anesthetic leper not.

Yours truly,

ALBERT S. ASHMEAD, M.D.

NEW YORK, July 5, 1898.

SOCIETY PROCEEDINGS.

TWENTY-THIRD ANNUAL MEETING OF THE AMERICAN GYNECOLOGICAL SOCIETY.

Held at Boston, Mass., May 24, 25, and 26, 1898.

FIRST DAY—MAY 24TH.

THE President, DR. PAUL F. MUNDÉ of New York, in the Chair.

DR. A. C. SINCLAIR of Boston delivered the address of welcome, and was followed by Dr. Edwin B. Craigin of New York, who read a paper, entitled

CONGENITAL PELVIC KIDNEYS OBSTRUCTING THE PARTURIENT CANAL, WITH REPORT OF A CASE OF VAGINAL NEPHRECTOMY.

He did not consider the subject of floating kidney, but only kidneys congenitally located wholly or in part within the cavity of the pelvis. Of forty cases reported, thirty-five were on the left side. Of twenty cases studied by Roberts, six were on the left side. Of fifteen which the writer found reported since 1869, fourteen were left kidneys. The kidney on the opposite side is usually present and in its normal position. In one case studied there was but one kidney. The arterial supply generally arises from the common iliac or sometimes from the aorta just above its bifurcation. Malformation of the genitals is sometimes present. Only five cases of distocia arising from this condition have been reported, and to these Dr. Craigin added a sixth. Mrs. M. was seen May 8, 1897. She was twenty-five years old, a native of Cuba, and had had two pregnancies, with difficult deliveries. She was then pregnant 8½ months. Behind the cervix was an elastic tumor, which reduced the internal conjugate to 7 cm. External measurements were normal. It seemed impossible for a child to be born per vaginam except after removal of the tumor. After incision of the vaginal wall the tumor was tapped and found to be a distended left kidney, fixed beneath the promontory of the sacrum. Vaginal nephrectomy was performed by first clamping the vessels and ureter at the hilus, removing the kidney close to the clamps, and then replacing the clamps by ligatures. A narrow strip of gauze was carried up through the wound and pressed against the pedicle. A few intermittent uterine contractions occurred during the afternoon, and at 2 o'clock the next morning true labor began. Seventeen hours after the operation a well-formed female child was delivered with ease. The mother made a good recovery and the development of the child was satisfactory. From the previous history and the easy labor after the operation there is little doubt that the kidney was the cause of previous distocia. The writer was unable to find reported another case of vaginal nephrectomy.

DR. A. LAPTHORN SMITH of Montreal then read a paper on

CASES OF PREGNANCY FOLLOWING VENTROFIXATION; IMPROVEMENTS IN THE TECHNIC OF THE OPERATION.

His conclusions, based upon about 2500 cases reported by forty-one operators, including 111 cases of his own, were as follows: (1) As far as curing retrodisplacements is concerned, whether retroflexion, retroversion, or anteflexion with retroversion, and also prolapse of the uterus, ventrofixation, with two buried silk stitches passing through the peritoneum and fascia, gives the most reliable results. (2) Ventrofixation should be reserved for cases in which abdominal section is necessary for other reasons, such as the breaking up of adhesions and the removal of the diseased tubes which caused the adhesions. When it is expected that pregnancy may follow some other operation may be chosen because (3) although pregnancy only followed in 148 cases out of about 2500, in thirty per cent. of these, or 36, there was pain, miscarriage, or difficult labor requiring obstetric operations. (4) When suspensio uteri was performed, that is the uterus attached to the peritoneum, only a few relapses occurred; but, on the other hand, the patients were free from pain during pregnancy and the labors were less tedious; neither did they require resort to serious obstetric operations. The uterus should therefore be suspended rather than fixed to the abdominal wall in all cases in which any part of the ovary is allowed to remain. (5) A third method, it is claimed by some, namely, the intra-abdominal shortening of the round ligaments, is preferable to either ventrofixation or suspension. This may be done either by drawing a loop of the round ligaments into the loop which ties off the ovary and tube, or in cases in which the latter are not removed, simply detaching them from adhesions and shortening the round ligaments by drawing up a loop and stitching it to itself for a space of about two inches. By this means the round ligament develops as pregnancy advances, and the dragging and pain, and other more serious accidents which are present in thirty per cent. of the cases of ventrofixation, are certainly avoided. (6) If the uterus is attached to the abdominal wall, the stitches should be inserted on the anterior surface but near the fundus. Complications have been more frequent when there has been too much anteversion. (7) As large a surface as possible should be made to adhere, by scarifying both the anterior surface of the fundus and the corresponding surface of the abdominal peritoneum, in which case one buried silk suture will be sufficient to keep the uterus in good position. (8) Several have reported incidentally that they knew of many cases of pregnancy after Alexander's operation, and that in no case was the pregnancy or labor unfavorably influenced by it. Alexander's operation should therefore be preferred whenever the uterus and appendages are free from adhesions. (9) The results of Alexander's operation are so good that even when there are adhesions, it might be well to adopt the procedure of freeing the adhesions by a very small median incision and then shortening the round ligaments by Alexander's method, after which the abdomen should be closed. This could be done without adding more than one-half of one per cent. to the mortality, which in Alexander's operation is *nil.*

DR. W. R. PRYOR of New York read a paper, entitled

THE TREATMENT THROUGH THE POSTERIOR VAGINAL CUL-DE-SAC OF ADHERENT UTERI.

He said that there is much information desired regarding the manner in which adhesions are produced. Certain patients give no history of labor, abortion, gonorrhea, or unclean intra-uterine manipulations, yet retroversion and fixation are apparent. In such cases little or no disease of the ovaries is found. It is most often seen in robust servant-girls. The period at which the displacement and adhesion occurs between the uterosacral and rectal structures and the uterus is unknown. Retroflexion and retroversion are equally marked. These cases are rare, the writer having seen but five. He classes them as congenital and incurable by any known operation. As we commonly meet with adherent retropositions, they can generally be traced to abortion or labor followed by sepsis, and some to gonorrhea. When gonorrhea is the cause, the tubes are most damaged, and the adhesion is of the least degree. In patients recently pregnant, the adhesions are most pronounced. In all cases adnexal disease is more extensive than is revealed by digital examination.

In all operations for the correction of these displacements, the first step is to free the uterus, then to treat the tubal and ovarian disease, and finally to endeavor to retain the replaced uterus in the normal position. An anterior or posterior fixation of the uterus will prevent its ascending during pregnancy. Any operation which will interfere with a future pregnancy should be condemned. The operation through the belly is more free from bad influence over subsequent pregnancies. The question of the position of the uterus is not alone to be considered. The only objection which can be made to hysterorrhaphy is that in some cases the removal of the ovaries and tubes is necessary, which would not be if treated by another route. Where there is fluid, the result of inflammation, if infected, its escape is necessary. This infection is especially likely in case of occluded tubes. Hemostatic sutures are unfortunate because they strangulate the tissues, limit repair, and lock in discharges. The speaker enters the pelvis through the posterior cul-de-sac. With this incision properly made, and the patient in a certain posture, the operator can see as much as through an abdominal incision. He can incise the diseased tissues as much as necessary and leave them oozing, suturing only when large portions of the ovary are removed, or when small vessels have been opened. This operation enables one to apply conservatism in a class of cases, and in a manner which one dares not attempt by any other operation.

The speaker had operated fifty-one times through the posterior cul-de-sac. All these patients were well after three months, and the uterus in good position, with one exception. The operation is as follows: After thorough preparation of the vagina, the uterus is curetted. Selecting the fold behind the cervix which marks the reflection of the vagina, he enters the cul-de-sac of Douglas, and makes a careful digital exploration. He then introduces a retractor and lifts the uterus into the abdomen and introduces several gauze-pads into the pelvis. Then the patient is thrown into an exaggerated Trendelenberg position, and one may see and treat the adnexa as desired. He excludes all cases showing pus. After the completion of the operation, the pelvis is wiped dry and several folds of iodoform gauze are introduced into the incision. These and the uterus are replaced *en masse*. The uterus is kept in position by gauze lightly packed in the vagina above the levator ani muscle, and this is held in place by a stout roll placed transversely. A self-retaining catheter is inserted into the bladder, and the sphincter ani dilated. From seven to ten days later the patient is placed in the Sims position, and the dressings removed and renewed under chloroform anesthesia. The patient is out of bed in 2½ weeks, and vaginal support is maintained for six weeks. The operation succeeds perfectly, several patients having become pregnant. Two have been successfully confined. The speaker seeks by this operation to sever adhesions and to obliterate the cul-de-sac and form a mass of lymph between the cervix, uterosacral structures, and the rectum. The resulting scar holds the cervix upward, and the body of the uterus is thrown forward by the intra-abdominal pressure. All replacement operations which succeed obey one of two rules: either the corpus uteri is fastened high and forward, or the cervix high and backward. The first fixes the body of the uterus, while the author's operation leaves it free. The uterus is limited in mobility in one direction—the downward movement of the cervix. The after-treatment is troublesome, and must be faithfully carried out.

The discussion which followed the reading of Dr. Pryor's paper was general, and fully brought out the views of those present on the subject of fixation of the uterus. Dr. Kelly said that the operation so highly commended by the essayist is a perfectly rational one from a mechanical standpoint, but presents certain difficulties in its practical employment. Personally, he prefers the operation of hysterorrhaphy. He has performed this operation 410 times since 1889, and with most satisfactory results in each instance. Eighteen or twenty of the patients had become pregnant afterward, and with one exception, nothing unusual had marked the gestation. He does not care for Alexander's operation. The round ligaments are not designed to hold the uterus forward except during pregnancy.

DR. A. PALMER DUDLEY of New York said that he has determined never to perform ventrofixation again unless positively necessary. He has never made use of buried sutures in these cases but in one or two instances, and then he was compelled to remove them. There is always less reflex trouble if pregnancy follows an Alexander operation rather then ventrofixation, but there is danger of the occurrence of hernia. He objected to the production of scar tissue in the floor of Douglas' cul-de-sac, as in Pryor's operation, as scar tissue is always tender, and in this locality may give rise to pain or reflex disturbances.

DR. CHARLES P. NOBLE of Philadelphia said that, in his opinion, ventrofixation should be abandoned; that suspension of the uterus gives the best results.

DR. HERMAN J. BOLDT of New York said it is impossible to arrive at a satisfactory conclusion as to which is the best operation, as the opinion of each operator depends upon his personal experience. In cases of posterior displacement with firm adhesions he approves of

opening the abdomen and performing ventrofixation. He is inclined to think that Alexander's operation gives less dissatisfaction and less trouble than any other method, provided, always, that the cases are carefully selected.

DR. MATTHEW D. MANN of Buffalo said that he prefers Alexander's operation. If adhesions are present, it is desirable and proper to open the posterior cul-de-sac, break them up with the finger, and then carry out Alexander's technic. If there is extensive disease of the tubes and ovaries, the abdomen should be opened and the organs removed, the operator then having an opportunity to cure the displacement, either by shortening the round ligaments or by performing ventrofixation. It is a mistake to employ non-absorbable ligatures in the operation of ventrofixation. Under such circumstances chromicised catgut ligatures alone should be used.

DR. GORDON said his experience with Alexander's operation has been limited, but very unfavorable.

DR. H. T. HANKS of New York said that the many reflex disturbances which occur after ventral suspension and fixation are due to the fact that the uterus is fixed too firmly in the median line.

DR. E. C. DUDLEY of Chicago said that in those cases in which the uterus is replaceable the indication for Alexander's operation must be very limited. There is no normal position for the uterus. It is practically a question of normal movement of the uterus. If the organ is permanently fixed it makes no difference where it is; it is not normally placed. For that reason the operation of permanent fixation should be condemned.

DR. HUNTER ROBB of Cleveland said that many patients are operated upon unnecessarily. Many get well without any operation whatever. Where diseased tubes and ovaries are present and at the same time a retroflexed uterus, the removal of the tubes and ovaries, and separation of the adherent uterus will do all that is necessary in many cases.

DR. JAMES R. CHADWICK of Boston said that he prefers Alexander's operation whenever it is suitable. He had performed it more than two hundred times and had never seen hernia occur in a single instance.

DR. A. F. CURRIER of New York said that the operation which preserves normal anatomical conditions should be the method of choice. There is probably no operation, however perfectly designed, that will not meet with a certain number of accidents. One objection raised to the Alexander operation is that there are two wounds instead of one. By a short median incision, shortening the round ligaments from the inside, whether by the method of Dr. Wylie or the modification of Dr. Mann, better results will be obtained than by any other method.

DR. J. RIDDLE GOFFE of New York said that he had been waiting for some one to suggest an operation by which it would be possible to obtain support at the proper point, *viz.*, the uterosacral ligament. Next to the uterosacral ligament the proper ligament to utilize is the round ligament, and recognizing all the objections that have been made to Alexander's operation, and also to laparotomy, he has been shortening the round ligaments through the anterior vaginal fornix, with satisfaction to himself and success so far as his patients are concerned. The method consists in incising the vagina along the anterior wall throughout its whole length and dissecting the vagina from the bladder. From this longitudinal incision he makes a transverse incision at the cervix, passes his fingers over the top of the uterus and is able to break up adhesions. The round ligament is caught up on each side about one and one-half inches from the fundus, doubled upon itself, and drawn down, in which position two or three catgut sutures are inserted, the angle of the loop then being stitched to the uterus. This will shorten the round ligament two or three inches. By operating first on one side and then on the other the uterus can be retained in a normal position. He has performed this operation in every case of retroversion either with or without adhesions.

DR. ALEXANDER J. C. SKENE of Brooklyn said that he has tried all the operations mentioned and found that with one or two exceptions there is room for all of them. We are not in a position to decide positively which is the best. Not a word had been said about the suffering produced by scar tissue in the vagina. More trouble follows the presence of scar tissue in this locality than from abdominal section. Another objection to Alexander's operation is that many times the round ligament is absent, either congenitally absent or completely atrophied. He has specimens in which he has been able to demonstrate that there was not a particle of muscular tissue in the round ligament, and he knew that many of the Alexander operations are failures on account of defects in the ligament.

DR. BOVEE said that there are other factors besides the uterosacral ligaments and round ligaments that act as causes and as anatomic reasons for treatment of the retroverted uterus. A too short anterior vaginal wall will do as much harm in the way of producing retroversion of the uterus as relaxed broad or uterosacral ligaments.

DR. A. LAPTHORN SMITH said that the Alexander operation could be performed without ever causing hernia. He had never seen a case of abdominal section in which the round ligaments were absent altogether. He thought that Dr. Goffe's operation has a great future before it; if he can shorten the ligaments without leaving a scar on the abdomen it is certainly a great step in advance.

DR. PRYOR, in closing, said he had not intended to precipitate a discussion on Alexander's operation. In speaking of hernia he had eliminated his own cases; he thought the fault was not in the operator but due to some change in the dynamics of the pelvis. A woman's vocation will have something to do with it. The fact that Dr. Smith does not see hernia may be because he is not connected with a dispensary. Any man who has a dispensary practice will see herniæ, sometimes as large as a cocoanut. He knew of no better way to hold the uterus in position until the lymph is converted into a scar than by employing the vaginal dressing. The lymph is not inflammatory lymph, and the scars due to it cannot be seen after six months. There is no lymph found when the abdomen is opened later. This method does not cure all patients; there is a limit to it. The operation is not in-

tended to take the place of Dr. Kelly's operation; it is only to be used in adherent cases.

At the beginning of the afternoon session the topic

HAS ELECTRICITY CEASED TO BE A USEFUL THERAPEUTIC AGENT IN GYNECOLOGY?

was presented for discussion.

The subject was presented by DR. HENRY J. GARRIGUES of New York, whose paper was published in the MEDICAL NEWS for June 11th, with that of DR. EGBERT H. GRANDIN of New York.

These papers were discussed by Drs. Engelmann of Boston, Boldt, Dudley, and King of New York, Sutton of Pittsburg, and Smith of Montreal, all, with the exception of the last named, condemning the use of electricity in gynecologic practice, as in a majority of cases it not only fails to benefit the patient but does actual harm. Dr. Smith said that every year he cured two or three patients with electricity and sometimes many more. He knew about sixty living women who had been cured of fibroid tumors. In every case of fibroid he has tried to persuade the patient to submit to an operation, but when she would not consent, he has begun the electric treatment, and in many cases has cured her. In these sixty cases he used the galvanic current, and usually 125 to 150 milliamperes. The average number of sittings was thirty-five or forty. He had had ten absolute failures.

DR. HERMAN J. BOLDT of New York then read a paper, entitled

THE PORRO OPERATION, OR COMPLETE EXTIRPATION OF THE UTERUS?

After citing cases and describing the technic of the different operations he came to the following conclusion: In all cases of absolute indication for Cæsarian section the complete extirpation of the uterus should be preferred. The question arises: What would be considered an absolute indication for removal of the uterus?

1. All women who have a living child in utero at term or nearly so, and in whom the pelvic diameters are too small for the delivery of a living child *per vias naturales*.

2. When the child in utero is dead and infection of the organ has taken place.

3. In cicatricial atresia of the vagina to such an extent as to prevent delivery through the normal route.

4. When a neoplasm is present in the column of the uterus preventing the passage of a living child with safety to the mother.

5. In such cases of rupture of the uterus in which an abdominal section is indicated and suture of the uterine wound is unsafe.

6. In some cases of hemorrhage from the uterus subsequent to Cæsarian section, as in a case reported in which the operator had completed the uterine suture and although no blood oozed from the stitch-holes the hemorrhage from the vagina was so terrific that he found it necessary to change the ordinary Cæsarian section to the Porro operation.

In summing up the author came to the following conclusions:

1. Total hysterectomy should be performed in preference to a supravaginal hysterectomy, with extraperitoneal treatment of the pedicle.

2. The operation should never be performed unless absolute indications are present.

3. The uterus can be rapidly removed by applying clamps on each side: the difference in time consumed between a Porro operation and total hysterectomy is not more than half a minute. The elastic ligature is dispensed with and the proper attachment of the cervix in the lower angle of the wound nearly equals the time consumed in ligating the vessels and suturing the peritoneum after the removal of the uterus. When the child is dead in utero the organ should not be opened for the purpose of first delivering it, but the uterus should be removed *in toto* unopened.

The advantages of total extirpation over Porro's operation are: (1) Less danger of infection. (2) Practically no danger from secondary hemorrhage. (3) Less danger of intestinal obstruction. (4) A shorter period of convalescence. (5) Less danger of ventral hernia. There are practically no disadvantages.

DR. EDWARD P. DAVIS of Philadelphia said that in Porro's operation we have the best, quickest, and safest method of operating. He warned against opening the uterus if the child is dead; he had had the misfortune to make this mistake once, and thought that the sepsis which caused death was due to it. He had found it an advantage to apply the clamp as close to the ovary as possible and then to ligate and cut; four to six ligatures are necessary. When operating on the pregnant uterus one should bear in mind the presence of the artery which accompanies the round ligament, and that it is large enough to require ligation. He emphasized the point that one cannot decide upon a given delivery by the pelvic diameters. He had had four cases of contracted pelvis, in each of which the past history demanded Cæsarian section, One had been delivered by axis traction, and another had been delivered spontaneously at her own home. There is danger of wounding the ureter in operating through the lower uterine segment, but by keeping close to the cervix it will not be great. If a stump is left the relations in the vagina are less disturbed than if the removal is total.

SECOND DAY—MAY 25TH.

DR. HENRY J. GARRIGUES read a paper, entitled

OBSERVATIONS IN REGARD TO GENERAL ANESTHESIA, ESPECIALLY BY THE SCHLEICH MIXTURES,

which will appear in a future issue of the MEDICAL NEWS.

Following the discussion of Dr. Garrigues' paper DR. MATTHEW D. MANN of Buffalo read one, entitled

THE SURGICAL TREATMENT OF IRREDUCIBLE RETROFLEXION OF THE GRAVID UTERUS.

The alternatives in these cases are either to replace the uterus, or that being impossible, to empty it, the argument being that if the uterus is left displaced the death of the mother and child will result, whereas, if the uterus is emptied the mother may be saved, but the child will be

lost. This teaching should be changed, and if it be found impossible by the most improved methods, including the use of anesthesia, to replace the uterus, the abdomen should be opened and the fundus pulled up by the hand introduced behind it. If the uterus completely fills the pelvis efforts at replacement through the vagina will fail, because when it is pushed up nothing can enter from above to take its place and the moment pressure is withdrawn from below atmospheric pressure forces it down again into its old position. Even if the uterus be soft and yielding it requires considerable manipulation to get it up, and this can only be done by letting the air in behind it. Pregnancy may exist when there are adhesions and these may be an insuperable bar to retroposition until they are broken up by the hand on the inside, thus giving another indication for operation.

DR. J. WHITRIDGE WILLIAMS of Baltimore read a paper, entitled

BACTERIA OF THE VAGINA AND THEIR PRACTICAL SIGNIFICANCE, BASED UPON THE EXAMINATION OF THE VAGINAL SECRETION OF ONE HUNDRED PREGNANT WOMEN.

He said that the first work in bacteriology of the vagina was done in 1887 by Connor, who examined thirty-one cases and stated that the vagina did not contain organisms capable of causing septicemia. Since then there have been one or two articles published each year on both sides of the question and by equally competent observers. His own work was based upon ninety-two cases and in these he did not find a single streptococcus or staphylococcus aureus. He found in several cases a white skin-coccus and in a number the gonococcus.

The difference in results obtained by different men is altogether a difference in the technic; all who obtained positive results introduced specula into the vagina, and so carried in past the hymen whatever organisms were at the entrance of the canal. The author's method is to spread the hymen widely apart with the fingers so as not to come into contact with the external organs of generation, in that way avoiding introducing organisms from without. The conclusions arrived at were: (1) That the vaginal secretion does not contain the streptococcus or staphylococcus aureus. Therefore the use of vaginal douches is unnecessary, and, in many cases, injurious. (2) The whole matter is one of technic. (3) The vagina does not contain pathogenic organisms. (4) It is possible that in rare instances the vagina may contain bacteria. (5) Death from puerperal infection is from infection from without and is due to a lack of antiseptic precaution on the part of the physician or midwife.

The President's address, by DR. PAUL F. MUNDÉ of New York, which followed the discussion of Dr. Williams' paper, was then delivered. He took for his subject

PUERPERAL SEPSIS.

Among other things he said that the first step in the treatment should be the freeing of the uterus from foreign substances, which may be done with the finger or the blunt curette which was introduced by the author. The cavity may then be irrigated with a mild solution of permanganate of potash. He very seldom employs bichlorid of mercury, and never stronger than one in ten thousand. Iodoform pencils do no particular good, and mask the odor and character of the discharge. The endometrium may be packed with iodoform gauze when it is desired to bring about contraction and reduction in the size of the uterus. The curetting of a septic endometrium removes tissues which have already undergone inflammatory obliteration of their absorbent vessels, and so does more harm than good by laying open fresh channels for infection. It is better to apply to such an endometrium a strong solution of chlorid of zinc, tincture of iodin, or iodized phenol, and then to wash away the loose débris with sterilized water and to pack the cavity with iodoform gauze, which should be removed within forty-eight hours unless the symptoms call for its earlier removal. When the uterine cavity is entirely empty, even though there be general sepsis, there is no use in giving intrauterine irrigations. When pelvic cellulitis, peritonitis, or salpingitis is detected, attention should be directed toward the local condition.

The medicinal treatment, unfortunately, is not satisfactory. If the patient can be kept alive by means of stimulants and nourishing food until Nature has thrown off the septic germs she probably will recover. If her stomach gives out and nourishment and stimulants are not retained, the disease wins. The objection to the coal-tar derivatives is that they mask the fever and depress the heart. The speaker does not hesitate, when the heart condition warrants it, to give phenacetin in 3 to 5-grain doses combined with caffein. A few hypodermics of ergot may be useful to keep up steady contraction of the uterus.

In conclusion, he spoke of the recently introduced treatment of septic infection by means of antistreptococcic serum. His experience was limited to three cases, all of which seemed desperate. From 3 to 6 hypodermics of 10 cubic centimeters of serum were injected at intervals of from four to twelve hours, and all three patients recovered.

DR. E. W. CUSHING of Boston then read a paper, entitled

THE INDICATIONS FOR PARTIAL AND TOTAL HYSTERECTOMY *via* ABDOMINAL AND VAGINAL ROUTES.

The following methods were considered: (1) Suprapubic amputation, extraperitoneal or intraperitoneal, where the cervix is cauterized and drained. (2) Total extirpation by the abdominal route, where the vagina may be left open, the peritoneum being open or closed. (3) Total extirpation by way of the vagina, either with the clamps, morcellation, or ligatures.

The extraperitoneal treatment of the stump has been abandoned by all except in exceptional cases. It may be employed when in an emergency it is necessary to terminate the operation immediately, as from shock from previous hemorrhage, in rupture of the pregnant uterus, for instance. The method of treating the stump intraperitoneally has been abandoned by the author because, when there is reason to fear infection from the cervical

canal, it is better to remove the entire cervix. As the healthy cervical canal is not septic, cauterization is not necessary if the entire uterine cavity has been properly cleansed and disinfected previous to the operation. Little of the cervix is left if the incisions which amputate the uterus are made obliquely. He considered the indications for removing the whole uterus or leaving a stump. The consensus of opinion appears to be in favor of total extirpation. This prolongs the operation twenty minutes to half an hour. The evil of the operation is the danger of wounding the uterus. There is also danger of infection of the peritoneal cavity from the vagina. The cervix is the seat of sexual sensation to a certain degree, and it is desirable to leave it unless there are indications for its removal. When hysterectomy is performed for malignant disease total extirpation should be selected.

When the cervix has been removed either the vagina may be left open for drainage or the peritoneum may be closed and the vaginal raw surface left open, or the vagina and peritoneum may be wholly closed. The speaker preferred to close the vaginal opening entirely and use a glass drainage-tube. The method of election is the closure of the vagina and peritoneum. In this way no raw surface is left. The combined method of operating complicates matters. He discussed the relative value of abdominal and vaginal hysterectomy and the matter of personal equation, the training of the operator being an important factor.

COLLECTIVE INVESTIGATION ON THE USE OF THYROID EXTRACT IN THE TREATMENT OF FIBROID TUMORS.

DR. WILLIAM E. MOSELEY of Baltimore based his remarks on investigations made in the Baltimore Medical College and five cases in his own practice. He had come to the following conclusions:

1. That whereas some patients can take large doses of thyroid with impunity, others are injuriously affected by small amounts, and one should begin with a minimum dose, say 3 grains daily, and increase it very slowly, watching the heart and kidneys carefully.

2. In cases of bleeding fibroids, thyroid has an influence toward checking the loss of blood, and in certain cases it is followed by diminution in size of the growth.

3. That its use in appropriate doses is followed by improvement in the general health, probably due to the cessation of loss of blood.

Nine to 15 grains was the maximum dose, 1 to 5 grains three times a day. The average duration of treatment was nine weeks.

DR. JOHN B. SHOBER of Philadelphia spoke of the administration of the extract of mammary gland. The first case was that of a woman thirty-two years of age, the mother of two children. Since the birth of the last child she had suffered from dysmenorrhea and menorrhagia, and for two and a half years had been conscious of the presence of an abdominal tumor, which rapidly increased in size. When seen it was as large as a pregnant uterus at term. The next menstrual period after using the mammary extract lasted but three days, and three months later the tumor had been reduced one-third in size. The second case was that of a woman thirty-two years old, who had a large irregular multilobular fibroid, accompanied by painful menstruation and menorrhagia. She was put on increasing doses of mammary gland in January, 1898. The periods have become more regular and less painful, and she has gained in weight and strength. In the case of a third woman menstruation had been painful and irregular for two years. She was put under treatment in November, 1897, and menstruation is now regular and free from pain.

He said the drug seemed to have an influence over the uterine tissue something like ergot; it produces cramps, and has the same effect on the growth.

DR. HOWARD A. KELLY of Baltimore read a paper, entitled

THE TREATMENT OF MYOMATOUS UTERI.

He took the stand that the treatment *par excellence* of myomatous uteri is myomectomy, and that hysteromyomectomy must be reserved for exceptional cases. We must take hysteromyomectomy down from its prominence, because myomectomy is the operation to be thought of first; it is the operation of election in treatment of fibroid uteri and has an important field in women under forty years of age. During the child-bearing period it should be performed no matter what the size or number of the tumors. Hysteromyomectomy is to be preferred after forty in most cases. The risks of myomectomy are greater than those of hysteromyomectomy. Scarcely any two myomectomies are alike, and it is a more prolonged operation. His list of cases includes ninety-seven operations in whites and blacks since October, 1890. The myomata occupied every conceivable position from the fundus to the cervix. From one, seventeen myomata were removed. These operations include tumors in all positions and of all sizes up to the size of a six-months' pregnancy. Some were subperitoneal, many were interstitial, and many submucous. In numerous instances he opened the uterine cavity extensively; in one case it was opened from the cervix to the fundus.

The technic is one requiring extreme care. As to asepsis, he always wears rubber gloves and has his assistants wear them. He begins with the largest accessible tumor, and grasping it with a pair of forceps keeps up traction, and peels back the tissues, often using gauze to force them back, handling the structures as little as possible. He takes extreme care in stopping hemorrhage, sometimes using as many as four catgut sutures tied tight. The hemorrhage is to be stopped by bringing the opposing surfaces closely together. In rare instances where the muscular tissue is soft the vessels may be pulled out and ligated, but this is exceptional. If the hemorrhage is not well under control both uterine arteries may be tied. One objection is that on opening the abdomen the uterus looks frightfully diseased, and the impression is that it is nothing but a mass of myomata and that it is impossible to leave behind any of the uterus. The fact is, the uterus is often greatly hypertrophied; there is always abundant uterine tissue to leave behind. One can work out a plan and determine just what kind of operation it is going to

be. A sound in the uterus will discover at once whether the tumor is low down or high up.

SHOULD NON-ABSORBABLE LIGATURES BE DISCARDED IN GYNECOLOGIC SURGERY?

was the subject next presented for discussion.

Papers on this subject by Drs. S. C. Gordon of Portland, R. Stansbury Sutton of Pittsburg, Charles P. Noble of Philadelphia, and Howard A. Kelly of Baltimore, who participated in the discussion, will appear in future issues of the MEDICAL NEWS.

DR. A. PALMER DUDLEY then read a paper, entitled

CONSERVATIVE OPERATIONS UPON THE UTERINE APPENDAGES,

and reported two cases in full.

DR. ALEXANDER J. C. SKENE of Brooklyn showed an apparatus for searing the pedicle with the electrocautery. It consists of a pair of forceps with a galvanic wire in one blade. The broad ligament is simply seared, and the hemorrhage controlled. The vessel or ligament is isolated, compressed, and the current passed through it for half a minute. For the pedicle of the round ligament in cases of ovariotomy he has a pair of curved pressure forceps with claws to prevent the pedicle sliding out. It is necessary to place a pad under the forceps to prevent any desiccation of the abdominal wall; he uses his fingers for this purpose. The object is to desiccate, but not cauterize. The stump is completely desiccated and may be dropped into the abdominal cavity without the slightest danger of hemorrhage. He has closed the abdominal wound more than one hundred times and never had a suggestion of hemorrhage in any case. The heat is never high—190° F; it is gauged by the amperemeter. The length of time required for securing an artery or any thing short of a large mass of tissue is very short. For a pedicle like the broad ligament a minute is amply sufficient.

DR. J. WESLEY BOVEE of Washington read a paper, entitled

PATENCY OF THE STUMP AFTER SALPINGECTOMY.

His attention was first called to this subject by the case of a young woman who came to him with a large abdominal tumor, and with a history that both tubes and ovaries had been removed, but there could be no doubt of advanced pregnancy. Since that time in five specimens of uteri removed months after ablation of one or both appendages, the canal of the tube stump was still pervious. He then described briefly these cases of his own, and also spoke of those seen by other writers. The consequences of the permeability of the canals of these stumps are pregnancy and peritoneal infection. But four cases of pregnancy have been reported, but probably others have occurred. To some women pregnancy following the removal of the diseased adnexa means eminent danger, and is a condition to be absolutely avoided. If ligation of the Fallopian tubes as now practised is not successful, some other method must be devised.

The topic

THE SURGICAL TREATMENT OF STERILITY; HOW FAR IS IT JUSTIFIABLE OR EXPEDIENT?

was discussed by Drs. Mann, Wylie, and others. Dr. Wylie's paper will be published later in the MEDICAL NEWS.

THIRD DAY—MAY 26TH.

DR. ANDREW F. CURRIER of New York read a paper, entitled

(*a*) REMOVAL BY ABDOMINAL INCISION OF THE REMAINS OF AN EXTRA-UTERINE FETATION OF FOURTEEN-YEAR'S DURATION; (*b*) THE METHODS OF CHOICE FOR THE REMOVAL OF HAIR-PINS FROM THE BLADDER IN WOMEN,

and was followed by DR. EUGENE BOISE of Grand Rapids, Mich., whose paper was entitled

POST-OPERATIVE SALINE INFUSIONS,

which will appear in a future issue of the MEDICAL NEWS.

DR. HENRY D. FRY of Washington then read a paper, entitled

STREPTOCOCCIC INFECTION IN CHILDBIRTH, AND THE APPLICATON OF SERUM-THERAPY.

He said that the opinion of different investigators varies a great deal. Of 83 cases reported, in 10 the result was good, in 8 it was inactive, and 65 doubtful. He thought that this varying opinion might be explained by the fact that bacteriology is still in its infancy. Bacteriologists are in dispute over many points, some claiming that the serum only protects against infection from the same variety of germs from which it is derived. The particular infection must be due to streptococci. The protective power of the patient must be such that the infection can be circumscribed. The earlier it is commenced the better is the chance for success. The danger of delay is that the suppuration may break through the walls and the infection become general; but marked beneficial results have followed injections delayed eleven, fifteen, and twenty-four days. The injection should be administered once a day, preferably in the evening. The initial dose is from 5 to 10 cubic centimeters, but larger doses may be administered in severe infections. If it has a good influence it usually shows itself after the first two or three injections, but its use should not be discontinued too early. The general treatment is sustaining; the local treatment is antiseptic to destroy the bacteria and limit the amount of toxin. Out of 119 cases there were 77 recoveries and 42 deaths. The author thought it unfair to condemn the treatment because the majority of cases in which it has been used have been improperly selected, and many of the patients were moribund before the serum was used.

DR. WILLIAMS thought a certain technic should be followed, and cultures taken directly from the uterine cavity. Investigations show that when the streptococcus is present there is a mortality of nearly fifty per cent. He did not think the value of serum as great as claimed. He had seen cases in which there was a chill on the fourth day with a temperature of 104° or 105° F., which suddenly dropped to 100° F. If these patients had been treated with serum the improvement would have been attributed to it.

DR. REYNOLDS spoke of the virulence of pure strep-

tococcic infection. Patients infected by the streptococcus or the colon bacillus, when treated early, promptly and thoroughly locally with the curette, usually get well. If these forms of infection are complicated by streptococci the prognosis is doubtful. He had seen many recover, but more died. His experience with pure streptococcic infection has been that the patient has died; he has had but one recover, and she was seen at the time of the initial rise in temperature before the chill. She was curetted and put on strychnin and tonics. He had not had an opportunity of trying serum in favorable cases, but had tried it in advanced cases, without altering the fatal issue. He thought the serum should not be used unless a bacteriologic examination by an expert shows the streptococcus to be present.

DR. NORRIS said he believed we would some day find that there are certain cases which will be benefited by antistreptococcic serum, but not until we are able to know more of the natural history. There is a difference between the diphtheria bacillus and the streptococcus; the diphtheria bacillus loses its virulence in a relatively short time, but in puerperal septicemia, when the streptococci have invaded the organism to such an extent as to produce fever and other changes, there is a modification of the organisms in the blood and serum. With the streptococcic serum we cannot neutralize the ravages of such virulent micro-organisms but can only hope to fortify Nature until she is able to neutralize the virus produced.

DR. WILLIAMS gave his method of technic as follows: First, the external genitals are disinfected thoroughly. Then the patient is placed in the Sims position, and a sterile Sims speculum introduced. The cervix is seized with forceps, brought down, and wiped with sterile cotton. The intra-uterine culture-tube is then introduced into the uterine cavity. It is guided by the eye and does not touch the outside of the cervix. In a majority of cases a syringe has to be attached to aspirate local contents. Both ends of the tube are sealed with sealing-wax, after which it is taken to the laboratory and the contents examined.

DR. PRYOR moved that a committee be appointed to investigate and report on the value of antistreptococcic serum in the treatment of streptococcic infection whether puerperal or not. The Chair appointed DRS. FRY, WILLIAMS, REYNOLDS, and PRYOR.

The following officers were elected for the ensuing year: President, Joseph Taber Johnson of Washington, D. C.; vice-presidents, Howard A. Kelly of Baltimore, and Albert F. A. King of Washington, D. C.; treasurer, J. Montgomery Baldy of Philadelphia; secretary, J. Riddle Goffe of New York; other members of the council, Charles P. Noble of Philadelphia, H. Whitridge Williams of Baltimore, Charles M. Green and George J. Engelmann of Boston.

DR. MUNDÉ, after thanking the Fellows for their patience and favors in helping him to expedite the meeting and make it one of the most successful in the annals of the Society, introduced his successor.

The meeting then adjourned to meet in Philadelphia on the fourth Tuesday in May, 1899.

REVIEWS.

CATAPHORESIS. By WILLIAM JAMES MORTON, M.D., Professor of Diseases of the Mind and Nervous System and Electrotherapeutics in the New York Post-Graduate Medical School. New York: American Technical Book Co., 1898.

THIS is an attractively bound and well-printed volume, largely a compilation of the author's earlier articles on electromedical diffusion. The first 50 pages comprise a historical résumé of the subject. The succeeding 100 pages, with 74 illustrations, are given up to the technic of the electric apparatus necessary for cataphoresis. The remainder of the work is devoted to the therapeutic application of medicaments by cataphoric diffusion. The instances cited in behalf of its value are too few and casual to establish entire belief. The successful production of local anesthesia by the cataphoric diffusion of cocain or guaiacol cocain is very encouraging and deserving of greater trial. From the space allotted we judge that a most grateful field for its application has been found in dentistry to anesthetize sensitive dentine and gums prior to operative procedures. The bleaching and sterilization of teeth with peroxid of hydrogen are also given as accomplished facts.

The armamentarium is unstable in its present evolution and the expense of it may be an obstacle to a rapid generalization of this method which has some latent merits.

THE DISEASES OF THE STOMACH. By WM. W. VAN VALZAH, A.M., M.D., and J. D. NISBET, A.B., M.D. Illustrated. Philadelphia: W. B. Saunders, 1898.

WITHIN the past few years a number of exhaustive works on the diseases of the stomach has been published in the English language, so that even without the present work this field, which after all is rather a limited one, would have been amply covered. Without wishing in any way to detract from the merits of the book of Van Valzah and Nisbet, it must be admitted that confusion may arise from such an excess in one field when other closely allied subjects, such as the diseases of the intestines, have received so little attention.

After a brief introduction the subject matter is considered under five sections: Diagnosis and Diagnostic Methods; General Medication; The Dynamic Affections of the Stomach; The Anatomical Diseases of the Stomach; The Vicious Circles of the Stomach. The general classification is good, but the subdivisions are most elaborate and much more so than our present knowledge would seem to warrant. In this respect this book offers a very striking contrast to the recent classic work of Riegel which is laid down on very broad lines. However, the individual chapters represent a large amount of excellent work and careful research. One who is familiar with the literature of the stomach will recognize statements from other works with citations of authorities. Indeed, the small number of references is very striking when one bears in mind how extensive is the amount of investigation on this subject.

The section on diagnosis occupies 137 pages, and is an able presentation. It is, therefore, to be regretted that the sections on absorption and "digestive work" are so meager. In the section on general medication there is a very full discussion on diet. The dynamic and anatomic affections of the stomach are very well discussed. It was an excellent idea to present the effects of disorders of other organs on the stomach, and the secondary diseases of the stomach under the head of the "vicious circle of the stomach."

The number of illustrations is not large, but they are well executed. Fig. 12 representing the Oppler-Boas bacilli is open to the criticism that it does not show the characteristic enlargement of the bacilli at one extremity.

The style is good although objection may be raised to the undue use of words and terms like dyshematopoiesis, hyperchromatic degeneration, etc. Errors are surprisingly few for so large a work. Attention may be directed to the misuse of the word acupuncture, on page 493.

The publisher's work is well done and the volume will undoubtedly meet success.

THE INTERNATIONAL MEDICAL ANNUAL AND PRACTITIONER'S INDEX. A Work of Reference for Medical Practitioners. Sixteenth year. New York: E. B. Treat & Co., 1898.

THIS *Annual* still continues to present, in a somewhat condensed form, the progress of medicine and surgery for the year. The same general plan and arrangement which has characterized the work in former years has been carried out in the present volume. An exhaustive exposition of each new advance in medicine, which would only detract from the value of a work of this nature, is not attempted; but the salient features of all the important advances and discoveries are mentioned, and the many references and copious index make the book a valuable aid to the general practitioner.

A short chapter on pathogenic bacteria by Shattock, well illustrated by general colored plates, has been added. The text gives many useful hints on the methods of examination of the hanging-drop and the staining of bacteria, but far more than this is required in the diagnosis of all but a very few organisms. In a future volume the author should detail isolation and culture methods.

INTRODUCTION TO CHEMICAL METHODS OF CLINICAL DIAGNOSIS. By DR. H. TAPPEINER, Professor of Pharmacology in the University of Munich. Translated from the sixth German edition by EDMOND J. MCWEENEY, M.A., M.D., Professor of Pathology and Bacteriology, C. U. Medical School, Dublin. New York and Bombay: Longmans, Green & Co., 1898.

THE purpose of this little work is to furnish the student with a guide, which shall be at once compact and reliable, to the simpler chemic and microbiologic data required in modern diagnosis. The small scope of the work renders completeness almost impossible, and yet there are contained within its 147 pages most of the necessary elements for modern laboratory work essential to the scientific establishment of medical diagnosis. As an elementary text-book it will unquestionably find a sphere. More than this it cannot hope to accomplish. The paper and illustrations are very poor.

THERAPEUTIC HINTS.

Treatment of Ascarides in Children.—

℞ Ext. spigeliæ fl. . . . . ʒ v
Ext. sennæ fl. . . . . ʒ iii
Ol. anisi } aa . . . . . gtt. iii.
Ol. cari }

M. Sig. One to two tablespoonfuls two or three times a day.

Formula for the Administration of Cascara Sagrada.—

℞ Ext. cascar. sagrad. . . . gr. xxx
Ext. frangulæ . . . . gr. xv
Pulv. aloes } aa . . . ʒ i.
Ext. gentian. }
Saponis . . . . q. s.

M. Ft. pil. No. LXXX. Sig. One pill at night. —*Pruys.*

For Amenorrhea.—

℞ Strych. sulphat. . . . . gr. ½
Ferri peptonat. }
Mangani lactat. } aa . . . grs. xx.
Scammonii }

M. Ft. pil. No. XL. Sig. Two to four pills at night.—*Gutaud.*

For Infantile Convulsions.

℞ Moschi . . . . . gr. viii
Acaciæ . . . . . ʒ ss
Aq. fœniculi } aa . . . ʒ i.
Syr. aurantii }

M. Sig. One teaspoonful every one or two hours. —*Solomon.*

For Chronic and Intractable Vulvar Eczema in Children.—

I.—Spray affected region three times a day with a two-per-cent. carbolic solution.

II.—Once a week make a light application of ordinary acetic acid.

III.—If there be spots of ulceration cover them with a powder composed of one part of finely powdered iodoform and two parts of alum.

To Relieve Neuralgia of Phthisical Patients.—Capitan prescribes the following ointment. A very small quantity is lightly applied, and the part covered with some impermeable material and absorbent cotton. The application must be discontinued as soon as the skin becomes even slightly reddened:

℞ Guaiacol } aa . . gr. lxxx
Methyl salicylatis }
Ext. belladonnæ . . . . gr. iiiss
Ext. opii . . . . . gr. iv
Vaselin } aa . . . . ʒ ss.
Lanolin }

M. Sig. External use.

In very acute cases, menthol (15 grains), antipyrin (30 to 45 grains), or bromid of potassium (80 grains) may be added.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIII. NEW YORK, SATURDAY, JULY 16, 1898. NO. 3.

ORIGINAL ARTICLES.

PRACTICAL ANESTHESIA.

BY S. ORMOND GOLDMAN, M.D.,
OF NEW YORK.

IT is generally admitted that deaths from chloroform are not infrequent. When it is considered that anesthetics are frequently given by inexperienced persons, and that patients are frequently improperly prepared and improper methods are employed to administer these agents, it is hardly surprising that fatalities occur. It is well known that complications, much less fatalities, rarely occur with experienced anesthetists. It is usually only the beginner who so frequently finds occasion to use the tongue-forceps and treat complications which do not really exist. Much has been written about deaths from chloroform. Little attention, however, is given by the average hospital junior or occasional administrator to the elimination of the evil effects of anesthetics, for no one will deny that proper narcosis will hasten rather than delay, as it usually does, convalescence from surgical operations. By a proper narcosis I mean a proper preparation of the patient and the administration of the anesthetic safely and skilfully. I therefore maintain that an ideal anesthesia should not only have for its object immunity from death, but that it should be so conducted that upon the patient's return to consciousness, it should be marked to the slightest degree by the knowledge that he has undergone narcosis.

We frequently hear of the advantages of chloroform over ether, and *vice versa*, usually by those who are accustomed to give the one agent only. No one is capable of judging the relative effects of the various anesthetics unless he has used each in a sufficient number of cases to become thoroughly familiar with them. While the future may disclose an agent for general anesthesia which will obviate the objections to ether and chloroform, we are at present limited to these two agents for the production of general anesthesia. One who has administered anesthetics to any extent is aware that there are certain types of cases in which the choice of the anesthetic and the method of anesthetization must be adapted to each individual case.

Proper Preparation of the Patient.—From one to four days preceding narcosis the patient should receive an active cathartic, as the mild mercuric chlorid or compound cathartic pill, in either case followed by a mild saline, my own preference being magnesium sulphate. He should be encouraged to drink as much water as possible, best accomplished by ordering a glassful at regular intervals during the day. If suffering from prolonged illness, and if hemorrhage or shock may be expected, he should receive once daily an infusion of normal saline solution, preferably introduced into the colon through the canalized Wales' bougie. The quantity should consist of about two quarts, and should be given about the middle of the day in the recumbent position, in which the patient should remain until it is retained. It is remarkable how much good can be accomplished by this simple procedure, as an uneventful narcosis and rapid convalescence may always be expected to follow it.

Preliminary preparation in emergency cases must, of course, be adapted to the exigencies of each case. If food has recently been taken, gastric lavage should always be employed, washing until all food particles have been removed. Patients who are not directly under the observation of the surgeon should be instructed not to take any food for at least five hours preceding narcosis, and this food should be of a variety easily digestible. It may be said that failure to observe these principles has frequently caused loss of life. The following case may be cited as mentioned to me by an anesthetist: A patient presented himself at a clinic in this city for operation, and with the surgeon's knowledge and consent was etherized. Shortly thereafter he vomited food, and ceased breathing in spite of all efforts of the surgeon and his assistants to resuscitate him.

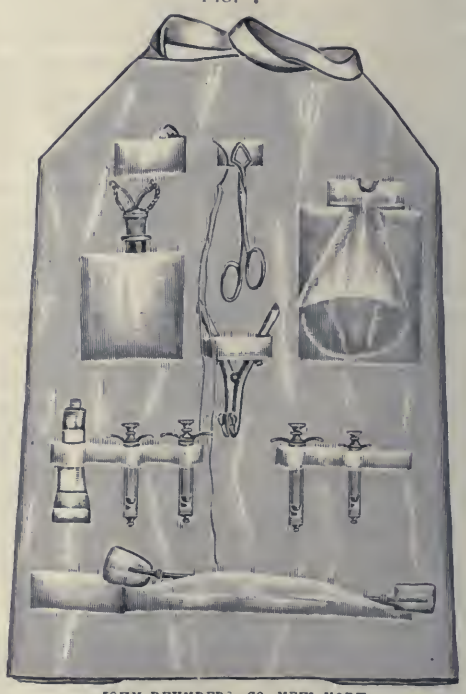
Thorough examination of the patient should never be omitted. The condition of the heart, arteries, lungs, and the urine need especial attention. The last is particularly important when open inhalers are used and little effort is made to reduce the quantity of the anesthetic to a minimum. I have frequently given ether in marked cardiac and renal disease without any deleterious effects following. I have never seen nephritis aggravated by the proper administration of ether. One case of acute exudative nephritis seemed to be benefited, for the day following narcosis casts and albumin, which were abundant before anesthesia, almost entirely disappeared. That nephritis can be produced or aggravated by the injudicious administration of ether by open inhalers

and supersaturation, I do not doubt, and I think may be a factor in its production, as well as of pneumonia following etherization. Transitory albuminuria and glycosuria I have observed following both ether and chloroform. They occur, however, so infrequently following a proper anesthesia that they need not be considered as possible complications. My custom has always been to examine the urine once, if possible, twice, preceding narcosis at each time that of the first voiding in the morning. I have also examined the urine two successive days following narcosis, and finally from one month to six weeks. These observations form the basis of an article in preparation, which will be presented shortly.

If it is necessary, hot concentrated broths of any kind may be permitted two or three hours preceding narcosis. It is advisable to have patients remain in bed for twenty-four hours preceding narcosis. False teeth should be removed, the patient should have on a woolen undervest and a night-robe, opening entirely down the front. The temperature of the room wherein the operation is to take place should be from 80° to 85° F., as should also that of the patient's room. Particular care should be observed in transporting the patient after narcosis. If this becomes necessary, he should be completely covered with woolen blankets, thereby preventing sudden chilling of the skin. The bed should have been previously warmed with hot-water containers, which may be placed about the patient, special care being observed that they be properly protected, as serious burns have been known to occur from negligence in this respect. The decubitus of the patient should be preferably the dorsal one, or, if necessary, the Sims' position. The head should be slightly extended and on a direct level with the body. This has a tendency to prevent falling back of the tongue, and facilitates the removal of saliva, which occasionally is troublesome.

It is the custom of certain operators to precede narcosis with the hypodermatic use of morphin and atropin, sometimes, in addition, whisky. The advantages claimed for this practice are that less of the anesthetic is required, the patient succumbs to its influence more rapidly, it tends to prevent cardiac and respiratory failure, and deepens narcosis. I have carefully observed many patients who were subjected to this practice; others who were not, and who underwent the most serious and delicate surgical operations that any patient is called upon to submit to. My observations have been that these so-called prophylactics are, in reality, positively harmful. The practice in no way reduces the quantity of the anesthetic required. Properly administered the agent can always be reduced to an exceedingly small quantity; that the patients succumb to the influence of the anesthetic sooner is not true. Patients can be anesthetized as rapidly without morphin as with it, and frequently more so; that this practice reduces danger of cardiac and respiratory failure I do not believe. I have seen accidents occur when morphin was employed which did not occur without its use. Further, morphin is a direct respiratory depressant, and, if for no other reason, this should contraindicate its use; that it deepens narcosis is too true; this is always undesirable, for the degree of narcosis should be such as to be readily controlled by the anesthetist. There is frequently a prolonged nausea and vomiting to be attributed to the morphin rather than to the anesthetic. Patients subjected to prolonged and painful operations in certain cases are, however, benefited by a hypodermatic injection of morphin, combined with atropin, upon complete return to consciousness. This is, however, to be decided by the surgeon, the element of anesthesia not to be considered.

FIG. 1.



JOHN REYNDER—CO. NEW YORK.

Author's apron.

Before beginning the narcosis the anesthetist should be fully prepared with instruments, stimulants, etc., to combat any emergency which may possibly arise. For this purpose I have devised the apron here shown It is arranged with pockets or compartments for holding the mouth-gag, tongue-forceps, sponge-holders, chloroform or ether bottle

containing a known quantity, hypodermic syringes, and needles. These are filled to the required amount with strychnin, nitroglycerin, atropin, to be used only as mentioned after operation, morphin, and digitalin (Duquesnal). The needles are not fastened to syringes, but are kept in a separate compartment and adjusted when necessary, this requiring but a moment. It will be seen these things are attached to the anesthetist, and can be immediately used when occasion demands. They are also unlikely to become broken from any cause. I desire to say that, while I always have these things with me, it is exceedingly rare that I find it necessary to use them. But not knowing in any individual case what complications may arise, no one who administers an anesthetic should fail to be provided with them. To do so is to invite disaster. The best way to treat complications is to prevent them. If strict attention is given to the narcosis complications will rarely occur. I may repeat that only the inexperienced so frequently meet dangerous symptoms, although they will occasionally occur in the hands of the expert.

Ether Inhalers.—These may be conveniently classified as open and closed. The first variety is made to allow a free ingress of air; the others so arranged that to the distal end is attached a rubber bag into which the patient exhales, and, to a certain extent, rebreathes the air (which is practically carbon dioxid).

The Allis and Sims inhalers are the most largely used of the open variety. Ormsby's modification of Clover's inhaler, as a closed inhaler, is that most frequently used in New York and vicinity. It may not be amiss here to mention the towel-and-paper inhaler. This consists of several layers of paper to give it consistency, with a towel externally, the whole folded to make a cone, into which the towel ends are packed, or in addition, gauze, sponge, or absorbent cotton is introduced upon which the ether is poured. This is, in reality, a closed inhaler, but is usually not so considered. The interior is so small that there is not sufficient space for the air in an ordinary respiration. Into this the patient exhales. The ether is immediately volatilized and expelled around the edges of the cone before the patient inhales again. This is forced upon the patient's face, and he is practically first asphyxiated, then anesthetized. Those who decry closed inhalers are usually the greatest advocates of this cone, whose one advantage is its cleanliness. The Allis and Sims inhalers are too well known to need description; they unnecessarily waste the ether and require considerable time to anesthetize the patient. The flannel used in the Allis inhaler is rarely changed after each narcosis. The Sims inhaler is easily broken, clumsy, and poorly adjusted. The Ormsby inhaler consists of a central, elliptical, metal part, to which is attached a rubber-bag. There is a pneumatic mouth-piece and a wire-basket for a sponge or a horse-shoe-shaped piece of metal perforated with holes, through which ether is poured upon a sponge. There is usually a contrivance upon the outer side of the metal piece for introducing air or replenishing ether without removing the inhaler from the patient's face. This inhaler, while efficient, is expensive, and not easily cleansed; it is poorly adjusted, and the ether and air contrivances are unnecessary.

To obviate these several defects, I have devised the inhaler here shown. It consists of a longer central cylinder and a shorter one telescoping into its distal end. Both are flanged. To the proximal or mouth-end is attached a solid, non-pneumatic rubber face-piece with rolled edges. A very thin rubber bag of fullest respiratory capacity is attached to the smaller cylinder; a metallic basket for gauze, inserted into any part of the cylinder, completes the inhaler. Its advantages are its evident simplicity, each part being removable, and thus rendered easily aseptic. The parts may be replaced at small expense. It is easily handled, economical, reducing the quantity of ether to from two-thirds to three-fourths of that usually used with open inhalers. One can anesthetize the patient in one-third the time usually required by the Allis or Sims inhaler. There are no ether or air replenishing valves to get out of order; when it becomes necessary to introduce more ether or air the inhaler is simply removed. Only gauze is used, freshly replenished for each case. Lastly, it can be employed also as an open inhaler if desired, for chloroform, by removing the rubber bag from the small cylinder, attaching the mouth-piece, and covering the open end of the inhaler with three or

FIG. 2.

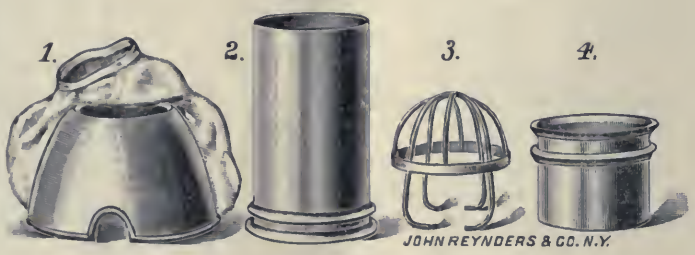
The author's ether-cone adjusted ready for use.

four layers of gauze, upon which the anesthetic is dropped. While I have used all the inhalers mentioned, I am convinced the closed variety is the inhaler *par excellence*. The patient by breathing into the inhaler inflates the bag, volatilizes the ether, which mixes with and is warmed by the exhaled air before being reinhaled. This inhaled air is ether and carbon dioxid, the last always essential for ideal etherization.

It may be said that certain large and plethoric patients, and especially those addicted to the use of alcohol, will not always tolerate carbon dioxid. Their condition is such that the elimination of carbon dioxid is not normal, and the blood quickly becomes surcharged. In these instances the removal of the bag and the small cylinder is desirable. For a chloroform inhaler the mask of Esmarch is most largely used in this country, but the small cylinder just described may be employed.

For operations about the mouth, pharynx, posterior nares, etc., in which preliminary tracheotomy becomes necessary, the following apparatus can be extemporized: To the distal end of two or three feet of medium-sized rubber-tubing is attached a glass funnel of a capacity of about eight ounces. This is covered with about four layers of a fine-meshed gauze, brought over and tied to the stem of the funnel. The end for insertion into the trachea is wrapped with gauze, covered with protective tissue. Chloroform is dropped on the taut gauze-covered funnel, the narcosis in every other way being conducted as if inhaled by mouth.

FIG. 3.



The author's ether-cone separated for cleansing.

Inhalation of Chloroform.—Vaselin should be applied to that portion of the patient's face immediately covered by the mask. It should be carefully understood, no matter which cone is used, that chloroform vapor should never exceed four per cent. of the air inhaled. (Snow.) This is best assured by giving the agent gradually, drop by drop, on several layers of gauze, through which air readily moves. Under no circumstances should the mask ever be saturated with chloroform. That so many deaths occur from chloroform is explainable largely by overdosage by this improper method. I have frequently seen the mask saturated with chloroform and the patient encouraged to breathe deeply; that they show signs of collapse is hardly to be wondered at. By dropping the chloroform just as the patient inspires will greatly reduce the quantity required. I have frequently successfully maintained chloroform narcosis in adults for two hours with 6 drams, and this without the so-called prophylactics. As soon as anesthesia is complete, the mask should be removed, permitting the patient to breathe the air. A little practice will teach one when to reapply the mask. The time to establish a complete chloroform narcosis in adults should never be less than five minutes. This was Snow's average time for chloroformization. To anesthetize in less time than this would necessitate concentration of the vapor with its attendant dangers. During the whole narcosis strict attention should be given to variations in the respiration, pulse, skin, pupil, eye-lids, lips, etc. Complete anesthesia is usually indicated by deep, rhythmical respiration, absence of corneal or conjunctival reflex, muscular relaxation, and insensibility to pain. It should be remembered that some patients will be completely anesthetized and the corneal reflex still persist. It is rarely necessary to push the anesthetic to the production of stertor in order to abolish this reflex. Relaxation of the eyelids during narcosis will usually obviate touching the conjunctiva. If this becomes necessary, gently pulling open the upper eyelid and touching its inner margin with the tip of finger will answer. In children the corneal reflex is quickly abolished. Here substitution of the palmar reflex will answer, or close attention to the respiration will always indicate complete anesthesia.

Variations in the pupil should always be noted. During primary anesthesia the pupil dilates. This always occurs also in very profound narcosis, which should always call for the removal of the anesthetic. In order to test the degree of narcosis where the pupil is dilated, a fresh supply of ether should be poured into the cone and applied to the patient's face. Efforts at swallowing, inhibition of inspiration, tonic contraction of the muscles of the lower jaw, grating of the teeth, all indicate imperfect an-

esthesia. When these symptoms do not arise too profound a narcosis is indicated. To continue the anesthetic would subject the patient to the risk of sudden death. The pupil during complete anesthesia should never be more than moderately dilated, and should always respond to light. Variations in respiration can be observed by watching the movements of the thorax or feeling the expired air against the anesthetist's tympanum or the dorsum of his fingers. Spasmodic movements of the chest indicate that respiration is being improperly performed, for very little air may be actually entering the lungs. When this condition exists with shallow, rapid, and high-pitched respiration, obstruction should be sought for and removed. The condition in the skin and mucous membranes should always be, at least, what it was when anesthesia was begun, the patient being faintly flushed. Sudden pallor or lividity call for immediate removal of the anesthetic. The skin should always be moist. Pulse variations are of greatest import. Increased rapidity of the pulse, if regular and of good quality, does not call for the removal of the narcotic. An irregular and feeble pulse, however, indicates its instant withdrawal. Efforts at vomiting, coughing, and articulation show an improper narcosis, and call for a continuance of the anesthetic.

Chloroform is preferable to ether when, for any reason, the latter does not act well. The change to chloroform will be found desirable and satisfactory. Conditions of the urine, indicating nephritis, acute or chronic, as well as acute pulmonary affections demand chloroform rather than supersaturation with ether by open inhalers. In alcoholics it is frequently desirable to begin the narcosis with chloroform and continue with ether after the patient is anesthetized. This may also be desirable in the excessively nervous and hysterical, the fumes of chloroform being, as a rule, more pleasant to inhale than ether. In obstetrics when it is usually not necessary to carry the narcosis beyond the second degree, chloroform should be used, but in acute hemorrhage, as in placenta previa, it should not be employed, ether being preferable. In operations about the face, necessitating the use of the cautery, ether being very inflammable, chloroform should be chosen. It is true that if ether is administered with closed inhalers, care being taken that the ether bottle is closed, this objection to ether can be overcome, as can also its use by night. In arterial disease, where for any reason increased arterial tension is undesirable, chloroform will usually be found preferable to ether, as ether is a direct cardiac and vasomotor stimulant and increases liability to rupture. Chloroform is extremely irritating when its fumes are subjected to decomposition by the action of any open flame which occurs in its use at night. Chloroform has certainly advantages in military practice, it being less bulky, cheaper, and economical when the quantity used is considered. Its higher boiling-point also makes it preferable for use in tropical countries.

The administration of ether, modified by chloroform or nitrous oxid, as before observed, may be preceded by chloroform until the patient is anesthetized, the narcosis thereafter being maintained with ether; or if preferable, nitrous oxid may be used primarily, to be followed by ether. It may not be amiss here to say that the reasons for using nitrous oxid are to eliminate the unpleasant symptoms frequently produced during the primary stage of etherization. I might repeat, if ether is properly administered these unpleasant symptoms will be the exception rather than the rule. Improper methods are probably the cause of these unpleasant symptoms and not the anesthetic.

A few words regarding nitrous-oxid administration may be in place. The gas-bag should be free from air. The inhaler should have two valves so fashioned that the patient does not rebreathe the same air. The cone should be closely applied, a hard rubber cube being first inserted between the teeth. The patient should be instructed to breathe deeply. As soon as cyanosis, stertor, and muscular relaxation are produced the gas should be discontinued and fresh air admitted. As soon as the patient shows signs of returning consciousness the gas should be readmitted. In this way I successfully maintain nitrous-oxid anesthesia for from twenty to forty-five minutes. If ether is to succeed the gas the closed inhaler should be closely applied, etherization then being conducted in every way as if the gas had not been employed.

Administration of Ether.—About one or one and one-half ounces should be poured upon the gauze, the patient being encouraged to breathe deeply. This is completely the reverse of chloroform administration. The cone should never be suddenly applied to the patient's face. As the upper air passages become accustomed to the vapor the cone should be gradually brought to cover the nose and mouth, excluding as much air as possible. Complete narcosis, which is manifested in the same way as anesthesia by chloroform, in non-alcoholic patients average five minutes. If ether is administered in this way the unpleasant symptoms will rarely occur. The same attention to respiration, pulse, pupil, and the color of skin should be given as with chloroform. It should be carefully understood that ether should not be continuously administered. After the patient is anesthetized the cone should be removed frequently,

permitting him to breathe fresh air; when reapplying the cone a very small quantity of the anesthetic will suffice for further narcosis. It is frequently said that one cannot with any accuracy gage the amount of ether necessary for any particular narcosis. In reference to this it may be replied that a narcosis lasting two hours can, with a closed inhaler in non-alcoholic cases, be maintained with from three to four ounces.

Ether should be administered in cases in which chloroform acts unsatisfactorily and in which dangerous symptoms repeatedly manifest themselves; in acute hemorrhage, as the vasomotor tone is stimulated while it is depressed by chloroform; in shock, when an anesthetic is necessary, ether is to be preferred. In general pulmonary emphysema it is far safer than chloroform.

Children take ether remarkably well. Its usual objection is its liability to irritate the respiratory mucous membrane. I do not think it more irritating, if properly administered, than chloroform. Old age is said to contraindicate ether, because of a preexisting chronic bronchitis in many cases. Properly administered it will not increase bronchitis. It is particularly indicated in old age since it is a cardiac and vasomotor stimulant. In fatty heart, endocarditis, syncope, if an anesthetic must be used, ether being less dangerous than chloroform, should have the preference. At night ether is preferable to chloroform, being less irritating to those about the patient than chloroform. Its liability to catch fire can be obviated with a little care.

Untoward Symptoms During Narcosis and Means Used to Combat Them.—Cyanosis. This may be due to falling back of the tongue on the epiglottis, malpositions of the patient, in which the head is lower than the body or in a continued Trendelenburg position. To remedy the first, pressure forward behind the mandibular rami will usually answer. If this does not suffice the tongue forceps may be applied or a tenaculum passed back near the base of the tongue and traction employed in a forward direction. If this occurs frequently it is better to pass a heavy silk thread through the tongue. This device is, however, very rarely necessary. The head should always be on a level with the rest of the body; this will obviate the second cause of cyanosis. Patients operated upon in the continued Trendelenburg position should, from time to time be placed in a horizontal position, as the pressure of the abdominal contents upon the diaphragm and the organs of the thorax impedes respiration. Mucus, saliva, blood or any foreign body becoming impacted in the pharynx or larynx may impede respiration. Removal with a sponge will usually answer. The impaction of loose teeth, or particles of undigested food, is prevented by proper preparation of the patient. If they should be the cause of obstruction the forceps or finger will usually dislodge them. If it does not, complete inversion of the patient and slapping the back vigorously will usually suffice. Efforts at vomiting indicate incomplete anesthesia. Gently pushing the anesthesia will abolish this reflex. If vomiting occurs the patient should be turned completely on the side with head slightly lower than the body. Before continuing the anesthetic the patient's mouth should be thoroughly cleansed. Blood entering the larynx will interfere with respiration. If not prevented it will cause death by asphyxia. If this occurs during the operation, the patient should be placed in the Trendelenburg position. If this does not quickly restore the patient tracheotomy or laryngotomy may become necessary. I have had but one case in which this became imperative. The patient was undergoing operation for extirpation of the external carotid artery, and excision of the floor of the mouth. From the inhalation of blood and mucus he stopped breathing. In this case the scalpel introduced into the cricothyroid membrane immediately produced relief.

Over dosage by a too concentrated or prolonged administration of an anesthetic is depressing, or if still continued, will cause death by paralysis of the vital centers. Ether causes death usually by asphyxia. Administered properly it always increases cardiac and vasomotor tone. If prolonged and concentrated, circulatory depression will result, death really being due to asphyxia. There is still a diversity of opinion as to whether chloroform causes death by cardiac or respiratory paralysis, the Edinburgh School and the Hyderabad Commission especially regard respiration of prime import, and recommend that strict attention to the breathing is the all-essential in chloroformization. More recent investigators, both in Europe and America, maintain that the pulse should be the anesthetist's particular care. Undoubtedly, chloroform may cause death first by respiratory paralysis, though most investigators claim (and correctly, I believe), that the heart or the circulatory apparatus fails in the vast majority of cases. Occasionally, they both fail at the same time. According to Hill of London, "chloroform produces a primary failure of the circulatory mechanism and secondary failure of the respiratory centre. The respiratory center fails to act from both direct poisoning by the drug, and from anemia of the medulla, produced by the fall of arterial tension. This is proven by the fact that the action of the respiratory center can be renewed by raising arterial tension; that chloroform more than any other agent

rapidly abolishes the mechanisms which compensate for the hydrostatic effect of gravity; that it abolishes these mechanisms by paralyzing splanchnic vasomotor tone; it also produces paralytic dilatation of the heart."

Treatment of Chloroform Syncope and Threatened Death by Etherization.—The anesthetic should be discontinued and fresh air admitted to the room. The patient should be quickly inverted by pulling him to the edge of the table until his legs hang over its edge. Raise the foot of the table and rest it on two chairs or a bench. This refers to those cases in which a regular operating-table is not used. Artificial respiration, preferably by Sylvester's method, about eighteen respirations a minute, should be practised. Rhythmical traction of the tongue, Labordes' method, eighteen times per minute, will stimulate respiration. Applications of cloths wrung out of very hot water over the region of the heart will stimulate it to increased action. The Koenig-Maas method of rapid compression of the chest, the thumb of one hand being applied over the heart, will stimulate both respiration and the cardiac beat. Direct insufflation of air into the chest by bellows (Fell) or by means of a soft rubber catheter introduced into the trachea, may sometimes be valuable. The anesthetist takes several deep inspirations, then exhales into the catheter to his entire extent. Introduction of a normal saline solution into a vein, the temperature being 105° F., or if into the rectum the temperature being 115° F., is of supreme value. The recurrent rectal tube of Dr. R. C. Kemp may be used, the water continually flowing. I have had excellent results in cases in which this was done. Hot coffee, introduced into the colon, is excellent. Atropin $\frac{1}{60}$-grain, and strychnin $\frac{1}{30}$-grain subcutaneously, being sure to have dosage large enough, are indicated. Amyl nitrite should never be used. It increases vasomotor depression. Alcoholic stimulants are contraindicated, as they tend to deepen narcosis.

Remote Sequels of Anesthesia.—These are nausea, vomiting, bronchitis, pneumonia, nephritis, and paralysis. Nausea, vomiting, and bronchitis are more frequently the results of improper preparation of the patient and of improper methods of administration than the anesthetic itself. In my experience nausea and vomiting have been the exception, following anesthesia either by ether or chloroform; if it persists, one-half ounce of hot water, or something cold, at varying intervals, with or without the addition of 10 drops of lemon juice, will often abate it. The factors in the production of pneumonia following ether are a predisposition on the part of the patient; supersaturation and inhalation of cold ether by open inhalers; septic inhalers; sudden chilling of the patient. Pneumonia is an exceedingly infrequent sequel of anesthesia. Bronchitis is occasionally seen. Nephritis, I think, is more frequently caused by chloroform than by ether. Proper administration of the anesthetic and the reduction to the smallest quantity possible to produce perfect anesthesia will reduce this complication to a minimum. Paralysis can be central or peripheral in its causation. The latter is most frequent, and is caused, usually, by pressure upon a supplying nerve or by pressure of a crutch or apparatus for maintaining the position of the patient. Central paralysis may be caused by rupture of a vessel in the brain. An improper method of administering the anesthetic is here the cause, as it is in so many other complications during or following narcosis.

The substance of this paper is based upon upward of 1400 cases of ether and chloroform narcosis actually administered (not merely observed) by the writer.

SUTURE AND LIGATURE MATERIAL; ABSORBABLE OR NON-ABSORBABLE?[1]

BY SETH CHASE GORDON, M.D.,
OF PORTLAND, MAINE.

IT is evident to the most casual observer in the profession that this question is still unsettled, if, indeed, it ever can be settled absolutely. It seems desirable that there should be as much unanimity as possible and the object of this paper is to invite the fullest and freest discussion. The different opinions held by men equally experienced and honest must leave the younger members of the profession in much doubt as to the course they shall follow. Sims revolutionized the practice of surgery by the introduction of silver wire in vaginal operations, and Emmet has continued it until to-day. Halsted uses it very extensively, but for other reasons than the original one offered by Sims. His principal reason is that it is not only capable of absolute sterilization, but is of itself a germicide. He buries it and closes the external wound with it. With these notable exceptions, this, like all other metallic sutures, which have had more or less favor, has been rather relegated to the lumber-room of surgery.

In the opinion of the writer the aseptic quality of silver wire entitles it to preference over nearly all kinds of non-absorbable material. Silkworm gut would come nearer to this than any other. Silk is perhaps more generally used than all other material of this class. Some surgeons claim that silk

[1] Read in the Discussion, "Should Non-absorbable Ligatures Be Discarded in Gynecological Surgery?" at the Twenty-third Annual Meeting of the American Gynecological Society, Held at Boston, Mass., May 24, 25, and 26, 1898.

should not be classed under non-absorbable, but too many instances of fistulous openings continuing until the ligature or suture has appeared, are evidence to invalidate such a claim. Every hospital in the world and nearly every surgeon of prominence can furnish such evidence. Silkworm gut can be impeached on similar testimony. Halsted uses no absorbable suture. If I understand this distinguished surgeon of Johns Hopkins correctly, he would prefer absorbable sutures provided he could be sure of freedom from septic germs. I may misunderstand his position. From all data at hand I have nearly reached the conclusion that the profession generally would, for most purposes, prefer absorbable material for both sutures and ligatures if they could be satisfied on two points: First, that it would not be absorbed until it had accomplished the object for which it was used, *viz.*, retain the parts in apposition until complete union had taken place, or in case of ligature of a vessel, until it is safe from hemorrhage; and, second, that the material is absolutely aseptic at time of use and will remain so until absorbed.

Assuming the second proposition proven let us examine and see what is absolutely necessary to hold the parts in apposition and how long it is necessary for a suture to last to do this. Repair of tissues when wounded, everything being aseptic, and the parts accurately approximated, is a perfectly normal, physiologic process, simply a regeneration of tissue. If no strangulation takes place (*i. e.*, interference with the circulation) repair begins at once and in twenty-four hours union is established by a plastic material which consolidates rapidly and becomes permanent. If by any means the surfaces could be retained in contact without the intervention of sutures the reparative process would go on much more rapidly, because no part of the circulation would be vexed by the pressure of sutures. Warren, in his "Surgical Pathology and Therapeutics," under the article, "Process of Repair," says, "Formerly the changes brought about in the tissues, by means of which repair was effected, were supposed to be caused by inflammation. It was thought that a smart inflammation was necessary to glue the lips of a wound together. Aseptic surgery has demonstrated the error of this view and it is now known that the two processes are quite independent of each other." This view of inflammation and repair was taught by Peaslee fifty years ago and I, as a disciple of his, have believed and taught the same during my whole professional life; that so far from inflammation being a part of the reparative process it is distinctly antagonistic and destructive to it. Warren further shows that while actual repair will take place in aseptic wounds in a very few days, yet complete solidification requires about three weeks. Therefore while superficial wounds will require sutures but a few days, deep-seated ones, like abdominal section, may need suture material that will last longer. It does not follow from this, however, that sutures need be buried if non-absorbable, for they will act to a greater or less degree as a foreign body and attract around them an exudate to encapsulate them, a material much less durable than normal repair tissue.

The absorbable materials for sutures and ligatures are catgut and kangaroo tendon. Dr. Marcy of Boston has used the latter for many years and is fairly entitled to all the credit pertaining to its introduction; his reports have been carefully presented to us and no one can question that in his hands it has been very efficient. My own experience with it has been limited and my observation among my colleagues does not encourage me to use it any more. It may be that it has not been carefully prepared or properly used. My chief objections to it are the short strands preventing over-and-over suturing, which I do very much in hysterectomy, and the possibility of its remaining unabsorbed too long and producing fistulous openings. I know of many instances of this, although it may have been due to faulty technic. Doubtless catgut is used more extensively than any of the absorbable materials. Its chief merit, in my experience, is that it rarely fails of absorption, and it is elastic, so that if a suture be drawn too close at first it soon gives enough to prevent strangulation of tissue. In this way one can do the over-and-over suture, an important thing where hemorrhage occurs in parts where much difficulty is experienced in ligating vessels in other ways.

The objections which are urged against its use are: First, the fear of infection owing to the extreme difficulty of rendering it strictly aseptic. So great is this fear that such men as Halsted absolutely refuse to use it or have it used by their assistants. Halsted claims that no specimen that he has examined is free from pathogenic germs; his authority is of more weight from the fact that all materials used at Johns Hopkins Hospital are subject to the most careful culture. Another objection is that if it is rendered absolutely sterile the fiber is to a great degree impaired and thus loses its strength. A third objection is that it is absorbed too soon and the tissues separate before complete union has taken place. While the fear of infection is paramount with some, in my opinion by far the larger number object to the material on the ground that it does not last long enough to prevent hemorrhage or to hold deep-seated tissues in apposition until union is solid. It is a very common expression among surgeons of my

acquaintance, "I should like to use catgut but do not dare to. I am afraid of hemorrhage." The feeling begins to be general that an absorbable suture is the ideal one, and one by one surgeons are coming to use it.

Since 1894 I have used no suture or ligature that was not absorbable, with the single exception of silkworm gut, and that only for closing the abdominal wound. In the latter case I include all the tissues with the silkworm gut, commencing from within and bringing the needle out, threading the other end and carrying it in the same way through the opposite side; this I believe is a preventive against stitch abscess, as I rarely see one. All my other ligatures and sutures are of catgut. In hysterectomy I use the over-and-over suture from beginning to end of the operation and nearly all ligatures used in the pelvic cavity are carried through the tissues by a needle and tied afterward. This is done to avoid slipping, which is so apt to occur when catgut is used in the ordinary manner. In commencing a hysterectomy I include a portion of the broad ligament, and after ligating as strongly as possible I carry the needle below the point of ligation, through the ligament, tying to the free end already used in the first ligature. In this way I secure the ligature from slipping from the ovarian artery, an accident which often happened before taking this precaution. The over-and-over suture is continued from that point on to and including the uterine artery, which I secure in the same manner. If the abdominal walls are thick I usually stitch the fascia with an over-and-over suture of very small catgut. It may not be necessary in ordinary cases, but seems best in the cases described. In finally closing the abdominal wound the silkworm-gut sutures should be drawn well up and tied just close enough to fairly approximate the surfaces, but not tight enough to depress the skin or in the least strangulate the tissues. Within two or three years I have allowed these sutures to remain at least two weeks and then removed every alternate suture, allowing the balance to remain from three days to a week longer By this method the parts are kept from any strain and hernia is almost unknown; in my opinion this is a very important step in its prevention; rarely is there any redness in appearance even at the end of three weeks.

For radical cure of hernia I have found the buried mattrass catgut suture to be sufficient, especially since I have made the incision freely above the internal ring. One modification of this operation, both of the Bassini and Halsted, I have made, which I like and shall repeat in a favorable case. Instead of closing the canal by buried sutures and then placing the cord between the surface and the fascia and closing the fascia over it, as in the Bassini, I place the cord above the fascia, after closing it separately, and then close the fatty and connective tissue, which lies between the fascia and the skin, over the cord (with catgut), instead of closing the skin over the cord as in Halsted's operation. This leaves the cord free from the skin and prevents adhesion to it. In all previous operations I have seen more or less swelling of the testicle, both in the Bassini and Halsted methods. In the instance in which I followed this procedure the fascia was thin and was closely bound down to the edge of the canal so but little room was left after the canal was closed. I feared if I did the Bassini operation it would press too hard on the cord. The result was that no swelling or soreness occurred in the testicle and the patient recovered with no discomfort from these usual complications. Catgut is the only suture that would have fitted such a condition without producing more or less strangulation. I do not know of any case of failure in hernia operations which has been in any way fairly attributable to the catgut suture. I do not use the chromicized gut for the reason that in many cases it is so hard that it will not be absorbed, and if by chance it should not be absolutely sterile very great harm would result from the operation, and even were it sterile and non-absorbable a foreign body is left which interferes with free circulation of the part, hence with perfect nutrition and repair.

Our object in hernia operations is to close the ring and canal perfectly throughout, and it is safe to assert that two or three weeks at most are sufficient for this, and as well-prepared catgut will certainly last that time, when buried, hence Nature's own union, when perfect, must be stronger than any artificial union. All exudate thrown out around a buried non-absorbable suture must be of much lower vitality than normal repair tissue, and consequently must be much more easily absorbed, thus rendering parts less resistant to pressure from within. The operations for hernia by injection of stimulating and corrosive remedies produce an exudate which lasts for a time and the patient is led to believe a cure is effected; but most of them give way after a time, the exudate having been absorbed. So far I have been entirely satisfied with the buried catgut suture, closing the canal, transplanting the cord by one or the other methods resorted to and uniting the skin by an over-and-over fine suture, or by Marcy's subcutaneous suture. Successful operations for hernia would seem to be as good a test as any operation in surgery, and if an absorbable suture accomplishes firm union of the tissues one cannot wish to leave a foreign body, which if it does anything must do harm

by interfering with normal circulation through surrounding itself by an exudate of low vitality. I have used catgut in all operations about the uterus and vagina, both for recent lacerations and those more remote and if at some time I have had partial failure it has doubtless been due to some fault in technic rather than to the catgut. I am sure that I have had many less failures from catgut than from the non-absorbable suture. There is this to be said, however, on the other hand, that when I used silver wire the profession was not doing aseptic surgery.

Perhaps one of the very strongest tests of the catgut suture is in the operation for cleft palate. This I have done repeatedly and, as a rule, with absolute success, never having had a *complete* failure since I began its use. Mr. Owen of London told me in 1890 that, in his experience, fully fifty per cent. of his operations were failures with silver wire. Occasionally I have found one or two stitches give way, leaving the cicatrix gaping, but generally the spaces have filled in by granulation afterward, so that no second operation was necessary. Mr. Owen admitted to me that he should like to try the catgut, for theoretically it appealed to him, but hitherto he had feared to use it owing to a lack of confidence in its durability for a time sufficient to produce union. Upon my statements regarding my own cases, he said he would gladly try it at the very next opportunity. I think Mr. Owen voices the general feeling about absorbable sutures; all recognize the difficulty attendant upon the use of non-absorbable ones, but have not full confidence in catgut, some fearing it for septic reasons, but the majority from lack of confidence in its durability.

Among my early operations of perineorrhaphy, like every one else, I used silver wire, but frequently removed it in four or five days and found everything well united, even in a case of complete laceration; indeed, in the first case of complete laceration for which I operated I ordered the sutures to be removed at the end of the fourth day. It proved a success but I confess that subsequently I did not dare repeat the procedure. All of us have seen how much the wire sutures cut the tissues when left a much longer time than this. The fault in part no doubt lies in twisting the wire too close and not allowing for the effusion of serum from the denuded surfaces and swelling.

In cases of vesicovaginal fistulæ I have had no opportunity of trying catgut, such accidents having almost gone out of the domain of surgery. I should certainly try it should occasion offer. I should not attempt to close abdominal incisions without the aid of silkworm gut, as it is retained longer. Some surgeons have had good results even in this operation with absorbent material, closing each layer separately. I think, however, they have mostly used the kangaroo tendon. I do not recall a case of hemorrhage following the ligation of arteries, where the accident was clearly the fault of the catgut, unless it may have been due to the fact that the ligature slipped from the tissues more easily than silk would have done. More care should be used in tying, otherwise slipping may take place. In using catgut in the ligation of small vessels embedded in the tissues the threaded needle is much to be preferred, as I have before said. It is a matter of very much importance to secure pure aseptic catgut, for here is where lies the principal danger. My own experience in preparing it has been very limited and altogether unsatisfactory. I shall make no further attempts in this direction. A friend in whom I have much confidence prepares his own by allowing the crude strands to remain in strong ether for two or three weeks, then transferring to bichlorid alcohol for a similar time, and lastly keeping in ninety-five per cent. alcohol. This does not weaken the gut and he has found no trouble from it in any way. My own preference for the commercial gut is the preparation which comes to us in alcohol. I use it from the bottles without boiling or further preparation. All efforts to more completely sterilize it has, in my experience, but served to weaken it, and so far as I know or suspect there has been no septic influence from it. It is usually uniform in quality and strength, and while expensive one can feel that it is safe to use it for all purposes. Within a few months I have used catgut which is sold in a dry state enclosed in wax paper, and from the statements of the manufacturer I am satisfied that the greatest care is used in its preparation. The only suggestion that I have to make in regard to this preparation is that the strands should be made longer to enable the surgeon to do over-and-over sewing. Care must be taken to moisten the catgut before using, otherwise it breaks easily. I think it is absolutely sterile.

My conclusions are: (1) All suture material unabsorbed must necessarily have more or less exudate about it. (2) Such exudate is of lower vitality than normal repair where tissues are just approximated and not strangulated. (3) A few days only are necessary to insure repair, if there is no infection, and therefore in cases where no great amount of strain exists absorbable sutures only are needed. (4) Where continual strain on the parts is inevitable, non-absorbable sutures should be used for at least two weeks, but should be so placed as to be removable. (5) For such sutures silkworm gut seems to be the best as it can be made sterile and kept so. (6) For all other purposes catgut is sufficient. (7) In-

flammation is always destructive to complete repair. (8) Inflammation is always due to infection. (9) Sterile catgut or kangaroo tendon should therefore fulfil all indications for suture or ligature material, with the exceptions named.

RHEUMATIC PHARYNGITIS.[1]

By LEWIS S. SOMERS, M.D.,
OF PHILADELPHIA.

W. E., male, aged thirty-eight years, came to my office on May 23, 1895, unable to articulate or move his head without suffering intense pain, attracting attention by pointing to his throat and expressing by gestures his inability to speak. Examination of the oropharynx showed both tonsils to be intensely inflamed and touching in the median line. Saliva was flowing in a constant stream from the mouth and the pharynx was filled with thick mucus. On the left side a collection of pus existed in the peritonsillar fibrous tissue, which was immediately evacuated with a bistoury. About one ounce of pus was discharged and there was some relief from pain, while the tonsil diminished in size sufficiently to enable a view to be obtained of the pharynx, which was inflamed and the walls covered with thick, tenacious mucus.

Temporary relief being obtained by the evacuation of the pus, he stated that he had always been robust and healthy, except that he had suffered for a number of years from rheumatism. The joints of the fingers and especially the feet were enlarged as is seen in long-standing cases, mobility of the articulations mentioned being much impaired, the metatarsal joints being rigid from the chronic changes. About once every year he would have an attack of articular rheumatism lasting for several weeks and always preceded by sore throat, which had not gone on to pus formation except in one instance previous to that time. The present attack commenced three days before his visit to the office and no other evidences of rheumatism had as yet developed. He was given an alkalin antiseptic solution to remove the mucus from the pharynx, and the salicylates were administered internally. Forty-eight hours after this treatment was instituted all pain and swelling had disappeared and the pharynx, except for a slight remaining congestion, was practically well. On the subsidence of the tonsillar and pharyngeal inflammation, an acute, violent attack of rheumatism in the previously affected joints made its appearance and continued for more than a week. One year later an identical attack again occurred, pus was evacuated from the tonsils, both being affected at this time, and the joints were again involved. The tonsillitis, or rather peritonsillar abscess, always preceded the articular symptoms and was relieved only by the administration of antirheumatic remedies.

In many cases of rheumatism the tonsils and pharynx present some evidence of the general diathesis, but it is not always as well marked as was seen in this patient. Usually suppuration of the peritonsillar tissues is not present as a part of the throat symptoms of the general affection, the pharynx merely showing evidences of slight congestion such as is observed in the familiar form of acute catarrhal pharyngitis. No definite group of symptoms or objective pharyngeal phenomena are seen when rheumatism affects the fibrous tissue of this portion of the upper respiratory tract. Every case varies, no two being alike, and from the local symptoms alone the diagnosis cannot be made, the general condition of the patient and the presence or history of rheumatism being essential to insure the successful treatment of the case.

A number of theories have been expressed as to the cause of the rheumatic diathesis, and until its etiology is clearly defined the laryngologist cannot give more than an incomplete picture of the affection as it manifests itself in the pharynx. To my mind it is definitely proven, however, that the rheumatic affection may be the cause of the tonsillitis, as we have seen in this case, or on the other hand articular rheumatism may result from infection through the tonsils. The latter statement includes, of course, the recognition of the bacterial origin of the disease. This has been well demonstrated in a case reported by Wagner,[1] in which the patient never had rheumatism previous to a severe attack of tonsillitis. The throat symptoms were followed by rheumatism of the knee, and bacteriologic investigation revealed the presence of the same micro-organism in both localities, thus proving the identity of the affection. The disease may primarily localize itself in the fibrous tissue of the pharynx with the formation of pus, the latter in the sequence of events being followed by the typical joint affection.

The symptoms of rheumatic pharyngitis and tonsillitis are not characteristic. The joint or muscle involvement may precede, accompany, or follow the throat affection in acute attacks and pain on swallowing may be intense. While the objective signs in no way explain the intense subjective symptoms, this disproportionate relationship is in a way characteristic in non-suppurative cases or where the pharynx alone is involved. Examination of the throat will show a moderate degree of congestion, some dryness of the mucous membrane, and a slight amount of capillary injection, the patient complaining of throat pain such as is produced only by a great degree of inflammation. In the majority of cases these peculiar subjective symptoms disappear without treatment in a few days, again making their appearance just as suddenly as they went away. This is more or less characteristic of the affection in the

[1] Read before the Northwestern Medical Society of Philadelphia, April 5, 1898.

[1] *New York Medical Journal*, No. 830, 1894.

early stages but other cases do not act in this manner, the inflammation increasing rapidly in intensity from the very outset and soon followed by a general explosion of the rheumatism; but not until the joints become involved is the nature of the disease ascertained.

Mercantius[1] has described what he considers a rather common group of symptoms referable to this portion of the respiratory tract under the name of acute rheumatismal pharyngomysitis. There is great pain on swallowing and only slight or not any redness of the pharyngeal mucous membrane. The pain becomes much intensified when the parts are subjected to pressure, but no other local or general subjective symptoms are present and articular rheumatism does not develop. The usual forms of treatment prove of no value, the symptoms only disappearing, and then very rapidly, when appropriate general antirheumatic medication is instituted, but local applications as in rheumatism of the joints are also of service. Following repeated attacks of acute rheumatic pharyngitis, or in patients with a marked rheumatic taint, a chronic pharyngitis may develop, in the latter instance without acute symptoms at any time. This chronic form of the affection is characterized by sore throat of mild severity which is more a feeling of local irritation than a definite pain, and this feeling is more or less constant, being accompanied by no objective signs except a slight thickening and restricted elasticity of the pharyngeal walls. The fibrous tissue alone is affected and inflammation of an acute character is never observed. It is usually seen after middle life, while no special age exerts any influence in the other varieties except as in rheumatism generally.

The diagnosis of the various forms of rheumatic pharyngitis must be based essentially on the history of the patient, the eccentric character of the subjective symptoms, the absence of special throat lesions, and the results of treatment. The protean character of the rheumatic manifestations, rendering a prompt diagnosis somewhat difficult, may be illustrated by the following case:

A. B., female, aged twenty-three years, was first seen January 19, 1898, complaining of irritation of the throat and the presence of a rash covering the entire cutaneous surface of the body. On examination the pharynx was found to be slightly sclerotic and the tonsils somewhat hypertrophied. Other than this nothing of special interest was found in the upper respiratory tract. The skin eruption consisted of macules varying in size from the head of a pin to a silver dollar. They were deep red in color, disappeared on pressure, and were irregularly round in shape. No subjective symptoms except a slight itching were present and the girl was otherwise apparently in fair health. She stated that seven weeks previous to that time she had had a severe attack of tonsillitis which confined her to the house for two weeks. At the end of that period the throat symptoms had practically disappeared, and on arising in the morning she found the skin eruption as described. Her physician treated the skin eruption for five weeks without making the least impression upon it, while the pharyngeal irritation still continued uninfluenced by medication.

When I saw the case the question naturally arose as to the cause of the apparent relation between the tonsillitis and the dermal eruption. From the subjective symptoms, and as a result of an examination of the throat and skin, it seemed impossible to make a diagnosis sufficiently accurate to allow of proper treatment. Further questioning elicited the fact that fourteen years previous she had had a severe attack of muscular rheumatism which confined her to bed for a number of weeks, and at irregular intervals since she had had slight attacks, but never of sufficient severity to incapacitate her from work. After a time the rheumatic attacks ceased completely, but she was subject to attacks of tonsillitis and pharyngitis, which never went on to pus formation, the last attack of the throat trouble, which was followed by the eruption, being worse than any she had experienced. Basing the diagnosis of rheumatism on the previous history, and using no local treatment whatever, but giving the salicylates and strychnin internally, the rheumatic nature of the affection was soon made evident. Within two days after this treatment was instituted the pharynx no longer troubled her, and within one week the skin eruption had entirely disappeared.

In all forms of rheumatic involvement of the oropharyngeal tissues, relapses are more or less frequent, usually at short intervals, and in a smaller proportion of cases a pharyngeal outbreak of the general affection makes its appearance at least once a year. The general treatment, with appropriate antirheumatic medicine, has been sufficiently pointed out in relating the history of the two cases, and on the salicylates alone can we depend to obtain favorable results. Local treatment of the throat is usually of little value but hot applications will sometimes prove helpful in acute cases. Pharyngeal massage to restore the tone of the parts may be tried in long-standing cases as an adjuvant to internal treatment. Electricity has been recommended and may prove of service in a few selected cases, both the galvanic and faradic currents being available.

WAR ARTICLES.

NEWS OF THE WEEK.

ONCE more the unlooked-for has occurred and the desperate dash of Admiral Cervera was the opportunity of Commodore Schley. This might well be called "The war of unexpected events," so rapidly are the conquests fairly forced upon our young but vigorous Navy.

Santiago de Cuba is not a place of importance to our Army or Navy, nor was it so considered until the cream of the Spanish Navy deliberately entrapped itself in the enclosed bay upon which the city is located; then its capture was necessary in order to secure a vantage-ground from which the fleet might be attacked by land forces while our vessels guarded the entrance to the bay. But again our plan went astray, for just as we waited with all confidence to hear the news of Santiago's capture after the two days of terrible fighting, the Spanish ships came in boldness or in desperation through the narrow inlet and in two hours were totally demolished.

The continued good health of our soldiers in Cuba is as unexpected as gratifying and yet we must not hurrah until we are out of the woods. True, the medical and surgical facilities and the arrangements for nursing the sick and wounded are admirable, considering the short time available for preparation, but over-confidence and a feeling that after all the dangers to be met were exaggerated, may be followed by a siege of disease which will overwhelm the entire hospital department.

Our men have not been in Cuba long enough for an epidemic of yellow fever to break out among them, but the danger of such a pestilence increases now with every day.

In the matter of diet the Spaniards in their plain living ordinarily have the advantage in warding off the diseases of a tropical climate. A Spanish soldier's rations, when he gets any at all, consist of one and one-half pounds of bread per day; all else he must buy himself. If he can get a little oil and an onion, with the omnipresent cigarette, he has no complaint to make, but if he can buy, beg, borrow, or steal a pint of light wine he is utterly happy.

Exact statistics are not as yet available, but observation so far tends to show that owing to the use of the modern rifles the instant deaths amount to nearly twenty-five per cent. of the total number of men hit by bullets, as against four and one-half per cent. during the war of 1861-64. But a brighter story comes from the hospitals where the wounded men, treated by modern methods, are recovering in greater proportions than the most sanguine dared to hope.

SUPERSTITIONS OF THE PHILIPPINOS; DANGER OF SNAKE-BITES; TAXES; NATIONAL LOVE OF GAMING.

[From Our Special Correspondent.]

WITH ADMIRAL DEWEY'S SQUADRON, OFF MANILA, PHILIPPINE ISLANDS, May 22, 1898.

IT is just three weeks to-day since the great battle, and the quiet of an Anglo-Saxon Sunday rests over the fleet. I understand the Spaniards here are boasting that a squadron of Spanish warships is on the way to drive Dewey from the Philippines, but little uneasiness is felt by the Americans as to the truth of this rumor. There is, nevertheless, some anxiety about the non-arrival of reinforcements, and speculation whether Aguinaldo, the rebel leader, who lately came on the "McCullough" from Hong Kong, will be of any real assistance to us. What the action of the rebels will be is uncertain. In the interior the natives are ruled principally by the monks, who are only a little less greedy for the Church than the Spanish officials are for themselves, and it is generally believed that the Islanders would be glad to be under American rule, though the Spanish priests represent the Americans as heretics, and as a people practically without religion, who forbid baptism and the religious solemnization of marriage.

There is a revolutionary society here which the Spanish call the "Free Masons," but whether it has anything to do with real Masonry or not I have been unable to learn. The priests denounce this society, and it is to be remembered that it was a priest who notified the governor of the plot among the members of this order a number of years ago to massacre the Spanish officials and priests, which had been communicated to him in the confessional by the wife of Pedro Roxas, one of the supporters of the revolution. Roxas, who was one of the wealthiest planters in the islands, after his property had been confiscated, was eventually shot. Horrible stories are told about the treatment by the natives of Spaniards who fell into their hands at that time. Many of the monks were slaughtered, some of them being dismembered a limb a day, while others were burned alive. It is clear that our proposed allies will have to be very gingerly dealt with, for they are ignorant and superstitious and have proved themselves as cruel as their Spanish masters.

A physician who has spent many years in these islands gave me an interesting account of some of the superstitions of the natives. They believe in witches and in evil spirits, and some of the means taken to exorcise these demons are violent in the extreme. For example, evil spirits are believed to hover about a pregnant woman waiting to snatch the soul of the unborn infant; and when labor com-

mences the *mabuling-hilot*, or midwife, is summoned in haste, for, as the midwife is supposed to be deeply learned in ways of dispersing witches, a doctor seldom assists at the *accouchement* of a native female. In case the labor is prolonged it is believed that evil spirits are holding back the child, and the midwife procures some gunpowder which is exploded close to the suffering woman's head, this being the approved method of driving away the evil influences supposed to be at work. When the child thus bewitched is finally born, it is placed on a pillow in an open door or window so that the air may facilitate the escape of the bad spirits, which are exorcised by burning three tapers on the face of the child, one on each cheek and the other on the chin. Sometimes the youngster receives three burns, but the ceremony generally goes off without accident. The priests do all they can to discourage these practices, but their efforts are of little avail. The natives who are converted to Christianity change their evil spirits for good ones and believe that an angel instead of a witch assists at the birth of every infant and follows it through life. Some sort of supernatural guardian they insist on having, so the priests encourage the belief in the angel. When anything is stolen a witch is called upon to find it, and no more wonderful stories are told of the discoveries of St. Anthony than the natives tell of the witches' aptness in detecting robbers.

Any one having much to do with the various primitive races is surprised at the similarity existing between their superstitions and traditions. The incantations of the natives of India and Asia are paralleled in the Philippines, and the witches are said to hold *sabbat* here as well as elsewhere. The belief that certain sounds have power over non-human presences seems to be universal, and the invocations used by the Philippine Islanders are said to be preserved in secret manuscripts, as are those of the peoples above mentioned. Another parallel is found in the tradition in regard to the formation of these islands. The natives, who of course originally knew nothing of the outside world, say that ages ago a giant bore the earth on his shoulders, but after a while he got so tired that he dropped it into the sea, wherein it sank so deep that only the mountains were above the water, these mountains being the islands they inhabit. The giant is, of course, the same as the Atlas of Greek mythology.

There is a greater proportion of quack doctors in the Philippines than in America, and the Chinese disciples of Esculapius have great influence. They generally use only vegetable medicaments, and in the cure of tropical diseases these solemn-looking Orientals have better success than their European rivals. They have a wonderful cure for the itch and the other skin diseases so common among the Islanders. On a previous visit to Manila I made the acquaintance of one of these Chinese doctors, and learned something of his method of treating certain diseases. Though he had been to Europe, he apparently knew nothing of surgery, and his remedies were very simple, quinin, opium, mercury, arsenic, and some mysterious Chinese drug, the name of which I have forgotten, being his principal curative agents. I understood that he never used leeches, although they are very plentiful throughout the islands. He claimed to have an infallible cure for pulmonary tuberculosis, which is very common here, and he was held in high esteem by his fellow practitioners on account of the many wonderful cures that he had effected.

The natives have a remedy for scorpion-bite which seems to be very efficacious. These bites cause a sharp, burning pain, and the part swells and becomes hard and white, but a cold application of crushed garlic relieves the pain almost instantly and reduces the swelling. The island abounds in poisonous snakes which are a real menace, the bites of several varieties almost always proving fatal. The most common symptoms of snake-bite are profound exhaustion, fever, and intermittent pulse, nausea, and great rapidity of respiration; the speech is indistinct and the pupils dilated. Snake-bite is so common in the Philippines that the American troops, if they come here, ought to be instructed how to apply ligatures to a bitten limb, and how to treat the victims of the deadly *daghong-palay*. From a considerable experience in this and similar climates, I am inclined to believe that our troops will suffer much annoyance from sore feet, for in the tropics, especially during the wet season, all leather shoes shrink badly, while the feet swell and become very tender. This annoyance may be obviated to a great extent by bathing the feet frequently, twice a day being none too often, and those who take the trouble to do this will be amply repaid in comfort.

As a rule the native women are very cleanly, many of them taking exquisite care of their persons. The younger ones are pretty and coquettish; they do not wear corsets, and in their native costume look very supple, feminine, and picturesque. There is more than the usual percentage of illegitimate children born in Luzon. One of the principal causes of this is the old custom of the prospective bridegroom's serving for a longer or shorter period in the household of the bride's parent, somewhat as Jacob served for Rachel. The priests do what they can to discourage these irregularities, but with only moderate success. Getting married is rather an expensive luxury here, as the Government demands a

tax for almost everything, from carrying on business to cutting down a tree. The tax on an ordinary carriage amounts to a sum equal to $12 a year, or $3 for each wheel, and the horse-tax is $4. There is a regulation requiring forty-days' forced labor for the public from each man during every year; there is also a poll-tax, an income-tax, innumerable stamp-taxes, excessive license fees, and extortionate fines The income-tax is often collected from people who have no settled income, and the system of fines is both arbitrary and dishonest. How this legalized robbery is enforced during the present condition of things at Manila I have been unable to learn. According to the latest information, meat is now between $2 and $3 a pound, and the other necessaries of life are in proportion. Business has been partially resumed in Binondo, on the other side of the Pasig, though it is evident that a state of panic exists throughout the city, for many of the foreign subjects are taking refuge at Cavité.

Judging from the character and disposition of the natives in Manila, they are probably spending these exciting times in cock-fighting and other amusements of a similar nature. The cock-fight is to the Philippine Islanders all that the horse-race is to the Americans, and considerably more. The owner of a fine game-cock takes a greater pride in it than in wife or family, and if the bird becomes ill, or is badly wounded in a fight, he is taken to the cock doctor with all speed. These functionaries are important personages, and they have receiving-houses where injured birds are treated. To staunch the flow of blood the wounds of the petted fowls are dressed with a mixture made from tobacco leaves and cocoanut-wine. It is no uncommon sight to see a native going to church with his favorite game-cock under his arm, and when he reaches the church he fastens the bird to a bamboo plug outside, goes in and listens awhile to the mass, then hurries back to his pet. Gaming of all kinds is the special delight of these people, and it would be interesting to know whether the great national lottery, which exists here the same as in Cuba, is as well patronized now as it was in times of peace. Despite the daily increasing evidences of famine within the city I doubt if anything will separate them from their love of gambling which will be found, literally their "ruling passion strong in death."

During a period of about ten years spent in various Oriental countries I have never seen such gorgeous sunsets as we have witnessed while lying at anchor in this beautiful bay, but the boys on the ships declare that the reddest sunset is gray and colorless compared with the glow which will light the sky when we finally bombard Manila.

NOTES ON THE AMBULANCE COMPANY.

By HENRY I. RAYMOND, M.D.,
MAJOR AND SURGEON, UNITED STATES VOLUNTEERS.

THE ambulance company is as yet an undeveloped factor in the medical department of the United States Army in the field. It is still, as it were, in the experimental stage, but bids fair to become in a short time a valuable adjunct to the division hospital in camp, and an indispensable attendant upon the army on the march. It is, indeed, the flying hospital, and when the army is on the move, and the division hospital, with its canvas and its medical and surgical armamentarium tucked away in its seventeen four-mule army transport wagons, twenty-five Red Cross ambulances, with their litter service and their readily accessible supplies both for subsistence and treatment of the sick and wounded, constitute the hospital on wheels officially designated "an ambulance company."

An army corps has for its three divisions a division hospital and an ambulance company, besides a reserve ambulance company for corps headquarters. A division, therefore, of a strength of more than 10,000 men, constituted of three brigades, and each brigade of three regiments, has its own specially designated ambulance service, consisting in our army of 104 privates, 7 stewards, 3 acting stewards, 6 medical officers (one commanding), and 1 line officer as acting assistant-quartermaster. The wheel transportation consists of twenty-five two- or four-mule ambulances, and three, four, or six-mule wagons, the latter for carrying tentage and field-supplies for the train.

The writer being ordered from the transport "Saratoga" in Tampa Bay to report at Chickamauga Park, Ga., for duty with the volunteers, was assigned by General Ward to command the ambulance company, 2d Division, 3d Corps. This company was not yet in existence, but was recruited in the following manner: Each of the regiments of the division (one regiment short) was called upon for its quota of thirty men, and to these were added thirty privates of the hospital corps who had been enlisted as such for a period of three years when the 1st and 2nd Arkansas regiments were mobilized at their State rendezvous. This aggregate of 270 men was assigned to the Division Hospital, which organization selected their allowance of 93 privates (3 of whom were to be appointed acting hospital stewards), and the balance, 177 in number, were assigned to duty with the ambulance company, the surplusage, or difference, between 104 (the recognized strength of the privates of the ambulance company, and 177 being intended for transfer to the reserve ambulance company after preliminary in-

struction and training in their duties as litter-bearers, etc.

The internal economy of an ambulance company is similar to that of a light battery of artillery. This ambulance company has been subdivided into three brigade sections, each under command of a commissioned officer, and further subdivided into regimental detachments, each in charge of a reliable non-commissioned officer, who is answerable to his brigade section commander, and the latter in turn to the commanding officer of the company. From this brigade organization it follows that if any brigade of the fighting force becomes of necessity separated from its division, the corresponding brigade-section of the ambulance company can be temporarily detached to accompany the separated brigade.

Perhaps the most systematic writer upon the organization and duties of ambulance companies in war service is Surgeon-Major Evatt of the English Army Medical Staff. His lucid and elaborate brochure, based upon his experiences as commander of a bearer or ambulance company in the Saukin expedition, 1885, and during the Afghan campaigns of the latter years of the same decade, is an extremely suggestive production and of such rarity that but one copy is thought to be extant in this country, that copy being in the possession of Lieutenant-Colonel Van R. Hoff, Surgeon, United States Volunteers, Chief Surgeon, 3rd Army Corps.

THE SOLDIER AND SAILOR IN ACTIVE SERVICE IN TIME OF WAR.[1]

By S. W. ABBOTT, M.D.,
OF BOSTON;
ASSISTANT-SURGEON, UNITED STATES NAVY, 1861-64; SURGEON, FIRST MASSACHUSETTS CAVALRY, 1864-65.

THIRTY-SEVEN years ago this month of May, I was returning home one evening from an evening school in my native town, when I learned that a public meeting was in progress in aid of the town military company which was just being recruited for three-months' service at the front. The meeting was mainly made up of the older citizens of the town, men of forty to seventy years of age, who were enthusiastically engaged in subscribing money for the fitting out of the company. Each citizen as he named the amount which he desired to give was greeted with rousing cheers. Little did they think that the war would last four long years and would snatch from them forever many of the best young men of the town.

I sat upon the rear seat of the hall and could not help catching the enthusiasm of the hour, and inwardly resolved to seize the first opportunity to join the boys. The opportunity came very soon for every one who desired to go. Whenever I see, at this day, a body of active, vigorous young men ready to leave home and the fireside to brave the hardships, the rigorous discipline, the dangers, and the risks of the camp and the forecastle I cannot help feeling a renewal of that old-time enthusiasm of 1861 and saying to them "God speed." At the same time I also feel that a timely warning with reference to some of the conditions which are likely to surround the young recruit may, perhaps, prove of some service to him in the future.

In order to state with any degree of accuracy the actual conditions of the soldier or the sailor in time of war, we may very properly divide the subject into certain topics and consider them separately. I shall present only those points which appear to be especially worthy of consideration as affecting the health of the young recruit while in active service. These are: (1) His food and drinks; (2) his clothing; (3) his shelter; (4) the age and size of the recruit, with principal disqualifying conditions; (5) special dangers and diseases to which he is subject and how to avoid them.

Food.—The food of the soldier in time of active service is determined by the best authorities upon the subject of food both as to its quality and quantity. In time of active service during war the food of the soldier differs essentially from that of the soldier in barracks in time of peace. The difference is largely due to the fact that the food of the soldier constitutes a considerable addition to the weight of the equipment which he carries, and every possible means is taken to reduce this weight by the use of such foods as are nearly absolutely free from water, which constitutes a very large percentage of all ordinary foods. The soldier in quarters receives good fresh bread cooked in the barracks or purchased for his use. Several times a week he also has fresh meat and fresh vegetables. Now all these articles contain a considerable quantity of water which is not essential to their value as nutrients. The potato, for example, has over seventy per cent. of water, and, when on the march, this would constitute a burden. Hence all such foods are discarded and the use of dry foods, or such as contain the greatest amount of nutriment to the least absolute weight, are employed.

The actual food of the soldier during the Civil War consisted mainly of salt pork, hardtack (or biscuit), and coffee. These three were the food of the army with such additions as could occasionally be had from the sutler. Butter was a luxury. Condensed milk was always in demand, and fresh beef was occasionally furnished when animals could be had for slaughter. This coarse but substantial fare was

[1] Abstract of an address before the Students of the Massachusetts Institute of Technology, Boston.

nutritious, but when long continued was liable to produce scurvy in consequence of the absence of fresh acid foods. A good mug of coffee twice a day served for the beverage of the soldier. In stating that the soldier, in time of war, has three meals a day I refer only to those quiet intervals when he is in camp and not on the march or making an extensive raid into the enemy's country. Often does the soldier go without food for a whole day and sometimes for two or more days when occasion requires it. Then hunger demands that he shall eat the first thing which may present itself which is at all eatable.

I recall very well a skirmish in September, 1864, when my regiment was drawn up in a cornfield in southern Virginia where the men were all partaking of the green corn without cooking it, pulling it from the stalks and eating it rapidly to satisfy their hunger. Upon each of these hills of corn there was growing a vine having large and fine-appearing fruit, the fruit of the passion-flower. Major Sargent, who was in command, being a good botanist, stated his belief that those must have been planted to serve as a food-supply, so we partook of them freely and without harm.

Sweet potatoes were dug from the fields; pigs, chickens, and other animals often helped to vary the food-supply; but, at the best, it was a very crude and unsatisfactory cuisine when compared with the hotel, boarding-house, or college restaurant, or what is far better, the domestic table of a New England home.

Drinks.—With reference to the drinks of a soldier, there is quite as much to be said as with regard to his food. While water enters more or less into the composition of nearly every known article of food or drink to a greater or less degree, and is also by far the most important of all beverages, it is also liable to become a source of serious danger in consequence of its contamination. With reference to alcohol, the best advice that can possibly be given is to let all alcoholic liquors absolutely alone. The best authorities, such as Dr. Parkes of the British Army and Dr. Woodhull of the United States Army agree in condemning alcohol as harmful to the service. One of these writers says: "The absence of liquor means a clear guard-house. Abundant liquor means a heavy sick-list, a large guard report, and a feeling of doubt as to the command." Spirits neither protect the soldier from cold, heat, nor malaria, and their use is productive of tenfold more harm than good. The abolition of the navy whisky-ration in August, 1862, was followed by better discipline, better order, and better health.

Upon the march the soldier usually has an opportunity to fill his canteen from running brooks by the roadside or at the various wells which are usually to be found in the neighborhood of farm-houses and cottages. It is always desirable to be on the lookout that such wells and streams are not in the immediate neighborhood of sources which always exist in the rear or near to such farm-houses and are liable by their proximity to contaminate these sources of water. As a general rule, water which comes out of fields, pastures, and territory generally unoccupied by human habitations is safe to drink, notwithstanding the fact that it may be considerably colored and less pleasing to the eye than that which is pumped from the ground in the more immediate neighborhood of villages. When troops go into camp for winter quarters it is customary to dig or drive wells at the end of the company streets, one or more for each regiment, the number depending largely on the facility of reaching water and the character of the soil. Such wells are usually safe provided they are kept from contamination. The principal beverage of the soldier in camp other than water is coffee. Its small bulk and easy method of preparation make it a desirable addition to the ration. It was invariably of good quality, so good, in fact, that Confederate soldiers were always on the lookout to exchange any commodities which they had while on picket duty for this article across the lines. I have dwelt somewhat at length upon this subject for the reason that, in my opinion, we were not then inclined to credit to polluted water so great a share in the causation of disease as actually belonged to it.

Clothing.—The clothing of the soldier is furnished by the Government and needs but little comment. As a general rule it may be said that closely woven woolen cloth forms the best material for the clothing of the soldier all the year round, in hot as well as in cold climates. It should be as light in weight as is consistent with durability. The whole weight including overcoat should not be more than fifteen pounds. One good blanket and a rubber poncho should form a part of the equipment of every soldier. This poncho is a most useful article because having a slit to admit the head it forms a good waterproof garment and may be used as a shelter against the rain or as a part of a tent. When spread upon the ground it serves as a temporary dining-table during an active campaign. The weight of the clothing and equipment of each soldier in active service is a matter of importance and in our service is distributed about as follows:

Clothing worn, 10 pounds; arms and ammunition (50 rounds), 19 pounds; camping apparatus, 6 pounds; water and rations, 3½ pounds; blanket, 5 pounds; shelter, 2 pounds; shirts, socks, and small articles, 4 pounds; total, 49½ pounds. This is a minimum. The soldier may, in certain branches of

the service, carry in addition a poncho, ax, hatchet and sling, spade, shovel, pickaxe, and frying-pan.

All the foregoing weights of articles are liable to increase; for example, three-days' water and rations increase the weight of food to nine or ten pounds, and every additional ounce of weight to be carried increases the fatigue of the soldier. It is customary to divide certain articles among several men, for example, such light cooking utensils as are carried on the march.

The Shoe.—One of the most important items in the clothing of the soldier, especially of the infantryman, is his shoe. A man who is liable to severe corns, bunions, tender feet, or weak ankles ought not to enlist as an infantry soldier. A good shoe should have a broad and low heel; it should not be made with narrow or pointed toes, and should not be too tight, since allowance must be made for considerable swelling of the feet in long and severe marches.

Shelter.—It is a prevalent belief that soldiers are well housed in wall tents or tents with flies and so constructed as to shelter completely from the severity of the weather. This, however, applies in active service only to the staff and line officers, since the carriage of so large a quantity of sheltering material would impose a great burden upon the quartermaster's department and interfere with the efficiency of the army in time of war.

Soon after the organization of the Union Army in 1861, it was found best to require each soldier to bear his own individual share in carrying his shelter, and a plan was devised by which each man carried one piece of tent cloth, five and one-half feet square, having buttons upon three sides. By this arrangement two men could fasten their two pieces together and make a temporary shelter for themselves. It was hardly long enough to cover each man completely. The weight of this shelter was only two pounds for each piece. It had the advantage of indefinite multiplication by means of the buttons, and when in winter quarters several pieces thus fastened together served for the roofs of the log houses then in use.

While on the march in good weather, the ground usually served for a bed, a light covering of leaves or pine boughs being placed on the ground under the shelter. In winter quarters it was customary to build log houses sufficiently large to accommodate from four to eight men in each, either with or without a flooring of boards taken from some abandoned house in the neighborhood. A fireplace of brick or stone was often made at one end and plastered with mud.

The position of the sailor is very different, each man having his own hammock, which is swung between decks and taken down in the daytime, and in the old wooden men-of-war these hammocks were carefully and neatly rolled up and taken on deck and stored in the nettings, where they afforded a good protection against the fire of small arms.

The Age of the Soldier.—The age at which the most effective service is rendered by the soldier may be stated as twenty-five years. The average age of the soldier in the Civil War was somewhat less, probably about twenty-three or twenty-four years. There ought to be a minimum age limit of twenty years, since those who enlist at seventeen or eighteen are not old enough nor well developed enough to endure the rigors of active campaigning. As I now recall the experience of 1861–'65, the surgeon's sick-list was largely made up of the young men or boys under twenty years of age who had not yet been accustomed to leave the comforts of the fireside and the home to engage in active life service. Men, too, who were of extremely light weight or were less than five feet in height did not usually endure hardship well. Parkes says: "To send young lads of eighteen or twenty into the field is not only a lamentable waste of material, but is positive cruelty." Napoleon said: "I must have full-grown men. Boys only serve to strew the roadside and fill the hospitals." The most efficient armies have been those in which the youngest soldiers were not less than twenty-two years of age. It would, however, be entirely proper to enlist young men of eighteen or nineteen, provided that a judicious discrimination could be given, as to the amount and quality of the work to be required of them.

So great is the difference in the mortality of soldiers and civilians that the best life-insurance companies to-day either charge extra rates upon the lives of soldiers or reject them altogether. I have said that the number who die of disease during the war is greater than those who die of wounds, since the Gettysburgs and Chancellorvilles and the Waterloos do not occur every day, but men are taken ill daily from various causes in every campaign and sometimes in large numbers. At the battle of Waterloo and the contributory battles of Quatre Bras, and Ligny, and Wavre on the 16th, 17th, and 18th of June, 1815, it is stated that 60,000 men were killed out of a total number engaged of 300,000. At the battle of Gettysburg, which lasted three days, the surgeons cared for nearly 30,000 men during the days which followed the battle, of whom nearly 7000 were Confederate wounded who were left upon the field. These numbers do not include the Confederate wounded or the wounded Union prisoners whom they took away with them on their retreat, and yet even these numbers are small

when compared with those who were disabled by sickness.

I do not think that young men who are contemplating enlistment sufficiently appreciate the fact that the risks which they run of becoming ill or even of losing life are at least eight or ten times as great as those which are encountered in the ordinary walks of life, and yet the history of the Civil War and the records of the Surgeon-General's office show that this is a fact. It is also true that the deaths from disease were far greater in number than those which resulted from wounds. The deaths from gunshot wounds upon the Union side alone in the Civil War were, in round numbers, 93,000. Those which were due to disease were estimated at 186,000 or twice as many. Those which were due to typhoid fever and diarrhea were 78,000 or nearly as many as those which were due to wounds. As a matter of fact the risk which each man ran of contracting typhoid fever in the Civil War was fifty times as great as he would have incurred if he had staid at home. Stating this in a different manner, out of every 65 men[1] 1 man was killed in action, 1 out of every 13 men died of disease and of unknown causes, and 1 out of every 30 died of typhoid fever and diarrhea. Such a mortality as this in any population in civil life would be reckoned very properly as a most appalling epidemic.

As an illustration of the losses in the Naval Service, the ship's company of the monitor "Catskill" now serving as defence for Gloucester harbor, numbered eighty all told, officers and men. During the six months ending with September 30, 1863, twenty-seven of these were either killed, wounded, or sent away from the ship in consequence of disability from disease.

There are certain ailments to which the soldier is liable in active service which with due care may be avoided; and first and most common are disturbances of the digestive organs. These are usually due to the action of some disturbing element in the diet combined with the influence of hot weather, and upon their occurrence it is desirable that the recruit should at once consult the medical officer of the command for such advice as he may give.

Another very common form of illness is malarial fever, for which the sovereign remedy is quinin. In consequence of a singular prejudice an unfounded fear has arisen to the effect that this remedy proves harmful. Under adequate advice as to the mode of its administration there need be no such fear. Having taken it in very large doses for many days in succession, I can say that it had no harmful effect whatever and I know this is the general testimony of those who have used it. Should the recruit be called upon to visit a malarious district, it is desirable to be stationed upon elevated ground and upon ground that is dry and porous and not marshy and damp. In such districts exposure to the damp air of the night should be avoided.

Sunstroke is a not uncommon incident to which soldiers are necessarily exposed. It may usually be avoided by keeping the head cool; moistened paper or leaves worn in the hat act as a preventive, and heavy work in extreme heat should be avoided.

Rupture is one of the accidents due to severe straining, lifting, or muscular exertion, and is actually present in from five to ten per cent. of men who have reached the age of forty-five. Should it take place in one who has never had a rupture a surgeon should be at once consulted and advice taken as to the best method of treating it. Severe rupture is usually considered as a disqualifying condition in a new recruit.

Scurvy is a disease which is not common among well-fed troops, but does occur when soldiers have been fed for a long period upon food in which fresh vegetables have been largely excluded. It was quite common in the Army of the Potomac in the last winter of the war. It used to be one of the serious causes of ill health among sailors, but in the present age of steam and consequently of short voyages, it is now of much more rare occurrence. A liberal allowance of lemons, lime juice, and fresh vegetables usually restores the victim to good health.

Personal Cleanliness.—Nothing is more essential to the well-being as well as the comfort of the soldier than absolute cleanliness in every particular. Frequent bathing and the liberal use of soap are even more necessary to the soldier than to the civilian. Some of the minor forms of disease which are due to the presence of parasites are very common in camp life. It is no disgrace to have contracted any of these ailments, but it is a disgrace not to get rid of them at once, and to take every precaution to prevent their recurrence. The young soldier must bear in mind that the luxuries and comforts of home life cannot be taken into camp, and that in this respect the camp with its rigorous discipline, its absence of the many conveniences that make one's home attractive, is yet a teacher, severe though it is, and one which will doubtless rarely fail to give young men a measure of independence and self-reliance which must, in the end, prove more valuable than any other sort of training.

The soldier's life in active service is one of hardships. He must necessarily learn to look out for himself and not to depend upon others. Very often

[1] See Scribner's "Campaigns of the Civil War." Phisterer's volume, pp. 70–71.

he may be placed in a position, as when he is upon picket duty or otherwise separated from his command, when he must cook his own food, and must under all circumstances look out for such repairs of his clothing and equipments as may from time to time be necessary. He is deprived of the refining influences of home life, it is true, but it is only the professional soldier of the regular service upon whom this should have a lasting influence, since the volunteer is constantly reminded of the close of the campaign or of the occasional furlough which will return him to the fireside or the home again.

CLINICAL MEMORANDUM.

TUBERCULAR MENINGITIS PRECEDED BY ACRODYNIC ERYTHEMA.

By JOHN A. BARKER, M D.,
OF PITTSBURG, PA.

ROBERT J., aged four and one-half years, was an exceptionally intelligent boy for his age. His mother died of pulmonary tuberculosis when he was a babe. His father is a stout, healthy man, who informs me that there is no history of tuberculosis or of any hereditary diseases except that of the mother. This boy had none of the diseases of childhood, but when about one year of age he was afflicted with spinal disease, the true nature of which we are unable to ascertain, which resulted in partial paralysis of the left leg, necessitating the wearing of an apparatus to support the member. He was presented at my office September 1st (last) to be treated for nasal catarrh. A careful examination revealed enlarged and swollen turbinated bodies of both nares which encroached upon the septum, and completely occluding the chambers. There was also a copious discharge of mucus. All the superficial lymphatic glands were enlarged to twice their normal size; the skin was pale, dry, and inelastic, the muscles were lacking in tone, and there were clubbed nails. The tongue was covered with a whitish fur, the teeth were nearly all decayed to the level of the gums, the breath was offensive, appetite capricious, digestion impaired, and there was constipation alternating with diarrhea. Urine negative except oxalates and phosphates in abundance. A tympanitic note was elicited over the apex of the left lung, and the breathing, excluding the puerile type, was tense and high-pitched, but there were no râles, cough, or expectoration. The voice was husky, and the respiratory movements were shallow and hurried. The heart's action was feeble, rapid, and irregular, and the pulse soft, compressible, and intermittent. The blood-count showed 2,900,000 per centimeter; hemoglobin, forty-five per cent. He was given a few small doses of the mild chlorid of mercury, and on the following day was ordered syrup of the iodid of iron and a ten-per-cent. solution of hydrozone as a local application for the nasal catarrh. A nutritious diet and plenty of fresh air were enjoined.

He returned September 14th. The blood-count then showed 3,000,000 per centimeter; hemoglobin, fifty per cent. The discharge from the nose had considerably diminished, nares were patulous, and the appetite and digestion were decidedly improved. He was directed to continue the treatment. I did not see him again until October 1st. He had been exposed the day previous to the first chilly winds of the season, which induced a relapse of his trouble, but in a more aggravated form, for the submaxillary glands were enormously swollen and tender; absence of voice and hearing, but no elevation of temperature. A few doses of the citrate of magnesia were ordered. The iron was discontinued, and small doses of Fowler's solution, in combination with potassium iodid, were given instead. On my next visit, October 2d, his left foot and leg were swollen, painful, and covered with a scarlatiniform rash, which in a short time changed to a blue color. The patient screamed with pain, which was greatly exaggerated on the slightest manipulation. Chloroform liniment and dry heat were applied to the affected member, and antikamnia was administered. On my return in the evening I was surprised to find that the right leg had become affected, and not a trace of the previously existing condition of the left leg was demonstrable. All the symptoms were exaggerated, especially the subjective symptom of pain, which could well be compared to the vivid picture of a crisis in locomotor ataxia, and which was but slightly ameliorated by administration of morphin sulphate hypodermatically.

On October 3rd the pain, swelling, and rash had subsided in the right leg and foot, and had moved to the left side of the body. October 4th. The left side of body normal and right side affected. October 5th. The right side of body normal and left arm attacked. October 6th. The right arm similarly affected and left arm normal. October 7th. Face and both ears attacked, the ears assuming a darkish-blue color, and the palpebra and ocular conjunctiva were hyperemic, and there was slight ptosis. No anesthesia or hyperesthesia was demonstrable. After these phenomena had repeated themselves a few times with provoking regularity, they finally reached the right ear, which assumed a blackish-blue color and simulated a gangrenous process. Sloughing, happily, did not occur, which, we believe, was prevented by the timely and frequent application of warmed ichthyo-lanolin ointment and dry heat, the latter being applied by means of a heated smoothing-iron, held a few inches from the ear. So intense was the pain that the patient had to be held while the light flannel cloth, upon which was placed the ointment, was being placed over the ear. I mention this because it is a happy way of applying medicaments to painful parts. The right ear remained in this condition for four days, when all the symptoms began gradually to subside, and by October 18th the ear had regained its normal shape and color, and, on the whole, the indications pointed toward a favorable termination. But, on October 22d, he had several attacks of vomiting, and, at the same time, complained of pain over the frontal sinuses and partial loss of eyesight. The pupils were equal and responded to light, but not to accommodation. An ophthalmic examination revealed hyperemia of the disks

and concentric contraction of the visual field; there was also a convergent strabismus. October 23d. The condition, except for attacks of vomiting, became more marked. Cerebral sedatives in the form of bromids were now administered and other agents discontinued. October 24th. Vomiting ceased, and there were present amaurosis, complete deafness, and clonic spasms of left leg and arm. October 25th. Complete left hemiplegia and clonic convulsions of right arm and leg. October 26th. A general convulsion, followed by coma; temperature, 102° F.; pulse, 65; respiration, 14. October 27th and 28th. No convulsions and semi-coma; the patient was able to take some nourishment and to communicate with those about him, but in a rambling, incoherent manner. October 29th, 30th, and 31st. The condition remained the same except the temperature, which was one degree lower. November 1st. The patient was seized with several convulsions, followed by profound coma, and death ended the scene November 2nd.

In making a diagnosis of the erythema, erythema simplex, erysipelas, angioneurotic edema, and sclerema were all carefully considered and excluded. Points of interest are: (1) The peculiar mode of onset by being preceded by acrodynic erythema. (2) The patient was always cheerful and not irritable, as is usually the case. (3) The absence of the usual premonitory headache. (4) The regularity with which the erythema migrated, and its apparent disappearance at the beginning of the meningitis.

THERAPEUTIC NOTES.

Strychnin in Alcoholism.—FEDEROFF (*Rev. de Therap.*, June 1, 1898), who has employed strychnin in the treatment of twelve cases of alcoholism has noted the following results: (1) The catarrhal symptoms subside more rapidly than they do in the cases in which the patient is deprived of alcohol and submitted to a strict regimen. (2) The neurasthenic attacks are favorably influenced by the strychnin, and the insomnia, as far as it is dependent upon nervous causes, soon disappears, the strychnin acting better in this respect than the usual hypnotics. Sleep becomes normal at the end of five or six days. (3) The senseless anger and the irritability which characterize alcoholics progressively subside. (4) The depression of spirits gives way to a more tranquil state of mind and the patients become courageous. (5) Other morbid symptoms, particularly the migraine, also pass away. (6) Unfortunately, the chief symptom, the craving for drink, is not influenced to any marked degree. "So that," says the writer, "though one must acknowledge the good effect of strychnin upon the nervous phenomena of alcoholism, it cannot be spoken of as a specific for this disease."

Hydrotherapy of Round Ulcer of the Stomach.—WINTERNITZ (*Blat. f. klin. Hydrotherap.*, May, 1898): The form of a round ulcer of the stomach seems to show that the nervous system has a part in its development, as is the case with perforating ulcer of the plantar region. The object of hydrotheraphy in these conditions is to cause the spasms of the vessels of the mucous membrane of the stomach to disappear. For this purpose baths at 10° or 12° C. (50° to 54° F.), and of three- to five-minutes' duration are given, and applications of cold cloths upon the abdomen, or a cold-water coil upon the cardiac region. The symptoms which yield most easily to this treatment are cardialgia, and hematemesis. The ingestion of bits of ice is a dangerous treatment for hematemesis. It is better to introduce cold fluid into the rectum, a measure which according to the experience of the author will reduce the intragastric temperature, and produce an intense contraction of the gastric vessels. This contraction is only for a short time, but it will often continue long enough to stop the bleeding. To make it even more certain pieces of ice may be introduced into the rectum.

New Method of Treating Tuberculosis and Other Pulmonary Affections.—WASSILIEFF (*Klin. ther. Wochenschr.*, No. 22, 1898) has adopted a method of treating pulmonary diseases by static electricity which if it does not cure phthisis, at least comes very near it. The patient seated upon an insulated stool inhales for five or six minutes a discharge of electricity which is directed toward his mouth by the physician. At first the patient feels a dryness of the throat and giddiness. Sometimes the head breaks out in a light perspiration. At the end of six or eight treatments the expectoration diminishes, the sleep is improved, and the night-sweats disappear. In certain cases there is cicatrization of cavities. Non-tubercular catarrhal and hypostatic pulmonary troubles can be entirely cured in from two to eight weeks. The author has had more than four-years' experience with this method of treatment, and the statements which he makes in regard to it are based on the observation of a large number of cases. He does not believe that the good effects noted are due to ozone.

Pyramidon in Nervous Troubles.—LANDENHEIMER (*Ther. Monatshefte*, April, 1898) has experimented with pyramidon, a derivative of antipyrin, upon more than one hundred persons suffering from some disturbance of nervous function. The headaches which so often occur during convalescence from various psychoses, almost all yielded to pyramidon in doses of 10 or 15 grains. From one-half to two hours were required for the medicine to take full effect. In the rebellious headaches of alcoholism, pyramidon was given with equally good result, the effect of the drug lasting nearly or quite ten hours. In three cases of cerebral tumor the headache was also stopped, but the dose required at first was 24 grains three times a day. This amount was afterward reduced to 6 grains a day. Painful cramps in the limbs of alcoholic patients were benefited, and one patient who took, without satisfaction, for an infraorbital neuralgia, 120 grains of antifebrin daily, found that 30 to 40 grains of pyramidon taken at a single dose early in the morning would give complete relief for 24 hours. In no instance was any toxic symptom observed. The maximum amount prescribed was 45 grains daily, divided into three doses, and continued for ten days. The writer considers pyramidon

a specific for rheumatism, but this view does not seem to be very well supported even by his own experience.

Use of Antipyrin in Sciatica.—KUHN (*All. Med. Central. Zeitung*) recommends hypodermic injections of antipyrin in sciatica, but relief from pain will follow only the remedy comes in contact with the affected nerve. Several times a day an injection of an aqueous fifty-per-cent. solution is made along the course of the nerve, a little below the middle of a line joining the sciatic tuberosity and the great trochanter. The results obtained by this treatment have been rapid and lasting, varying, it is scarcely necessary to add, with the intensity of the affection.

Charred Straw in Surgery, Especially Military Surgery.—KIKUZI of the Imperial Japanese Army (*Georgia Jour. of Med. and Surg.*, June, 1898) claims the superiority of charred straw over gauze as a dressing in surgery, and especially in military surgery, since it can be quickly prepared anywhere at little or no cost. As the dust from the charred straw will easily sift through a layer or two of gauze, the neatest method of application is to keep the charred straw in loose gauze bags, which are separated from the wound by a couple of layers of gauze. The gauze may be washed and used again after sterilization if great economy is necessary. The advantage of this new surgical dressing are thus described by its originator:

1. The absorbent capacity of charred straw has been proved to be much greater than that of gauze.

2. Charred straw is ready for use everywhere, not alone in the Orient, and it is easily prepared in large quantities, which is not the case with gauze.

3. With regard to cost, charred straw has the advantage over gauze. An average dressing of the last-named material costs about 1.6 francs (about 31 cents), while a dressing of the same size of charred straw costs only about 0.1 centime (less than 0.02 of a cent).

4. Charred straw is ready for use immediately after having been burned; that is, it is easily disinfected, whilst the preparation of gauze and its disinfection is a complicated process.

5. There is no need of transporting charred straw, as it can be obtained everywhere.

6. In regard to its softness, elasticity, and general usefulness, it differs very little from gauze.

From a military point of view, it is of importance that the large storage-room required ordinarily for surgical dressings may be dispensed with, since, in time of war, the preparation of this material will be carried on wherever it may be required. This observation of the necessity of storage in time of peace, of transportation in time of war, and its cheapness, are three very important points in which charred straw is superior to gauze.

As a dressing for poor patients it can be fully commended for its cheapness.

Influence of Abdominal Massage upon the Secretion of the Gastric Juice.—REED (*Med. Press and Circular*, May 4, 1898) expressed his satisfaction with massage especially deeply administered (*petrissage*) in patients suffering from gastric disturbances with lack of sufficient gastric juice or lack of muscular power. Massage increases the tonicity of the muscles of the exterior abdominal wall, as well as that of the muscles of the stomach and intestines, and it has besides an undoubted effect upon the glandular action of these organs. In some cases of chronic gastric catarrh the amount of free hydrochloric acid was finally restored under an energetic treatment by massage and galvanism, together with the administration of pepsin and hydrochloric acid for long periods—six months or less—with lavage for a shorter period. The conditions under which massage of the abdomen has been found in the writer's experience particularly useful are: (1) Chronic gastritis in all its forms excepting those accompanied by hyperchlorhydria. (2) Anacidity or subacidity, except when dependent upon acute gastritis or carcinoma. (3) Gastrectasia, not dependent on cancer. (4) Atonic conditions of the stomach walls, whether progressed to the stage of dilatation or not. (5) Displacements of the various abdominal organs including: (*a*) Gastroptosis; (*b*) nephroptosis, except in cases where the displaced kidney has become excessively tender on pressure; (*c*) enteroptosis. (6) Chronic intestinal catarrh, not complicated by deep ulceration. (7) Dilatation of the intestines. (8) Constipation from unknown causes. In many such cases massage often succeeds. (9) In a group of symptoms which comprise especially tenderness over a region three or four inches in diameter including the umbilicus as its center and a marked pulsation of the abdominal aorta in the entire epigastric region. These symptoms have been assumed to denote congestion of the solar-plexus. They are often met with in practice and may be the result of auto-infection from the gastro-intestinal tract. They are usually benefited by gentle kneading of the abdomen in connection with careful attention to diet. The following are the principal contraindictions for massage of the abdomen: (1) Ulceration in any part of the stomach or intestines. (2) Cancer of any of the abdominal organs. (3) Acute inflammation in any part of the gastro-intestinal tract. (4) Hyperchlorhydria. (5) Prolapsed kidneys which are acutely sensitive to palpation. (6) Aneurism of any of the abdominal or thoracic arteries. (7) During the menstrual period, when the flow is excessive or when there is a tendency to menorrhagia. (8) In fatty degeneration or marked dilatation of the heart and advanced phthisis, especially with a tendency to hemoptysis, abdominal massage should be practised—if at all—with much care and gentleness.

Carbonate of Creosote in Pulmonary Tuberculosis.—Gram of Copenhagen has found rapid and marked improvement of the pulmonary symptoms and of the general condition to follow the administration of large doses of this drug. Beginning with a single daily dose of 30 minims after the mid-day meal he advances to 30 minims three times a day, and never exceeds 90 minims three times a day. He gives preference to the pill form as follows.

℞ Creosoti carb. . . . . ʒ iiss
Magnesiæ . . . . . ʒ ss
Pulv. glycyrrhizæ . . . . . ʒ iii.

M. Ft. pil. No. C. Sig. To be taken after meals in number as directed.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SOME OF THE RESULTS OF FILTRATION OF CIVIC WATER-SUPPLIES.

FIVE years ago Hamburg had an epidemic of cholera, which was traced to the pollution of the drinking-water taken from the river Elbe. There were nearly nine thousand deaths. Altona, just across the river, received its drinking-water from the same river, and yet there were extremely few cases of cholera. The explanation was that at Altona the water was passed through filter-beds. Filtration of London's water-supply reduced the death-rate from typhoid fever eighty-six per cent. Filtration in Warsaw rid that city of typhoid, which had been extremely prevalent there. Ten cities of Europe have introduced filtration, with the immediate result of eliminating typhoid fever.

In this country, Lawrence, in Massachusetts, after suffering from several epidemics of typhoid, found health and immunity in a filter system. A writer on this subject has compiled the statistics of typhoid-mortality of twenty-four cities of the world during four years. In New York, for instance, the rate per one hundred thousand was 20.4, while in Berlin it was only 8, in Vienna 7, in Rotterdam 5.2, and in The Hague 4.9—these four cities using filtered water. In Chicago the rate was as high as 84, in Washington, 76.6, and the whole average of the cities using unfiltered water was many times higher than those using filtered water. The lesson is so plain and so positive that there can be no doubt of the absolute value of filtration for large cities, and it would mean to a place like New York the saving of hundreds of lives every year.

SOME LESSONS OF THE WAR.

To one who has not read between the lines of the striking events which have characterized the present war it may seem premature to philosophize or to dogmatize regarding the conclusions to be drawn therefrom. But it must be remembered that decisive, epoch-making occurrences have dominated the progress of affairs; history has been made rapidly and conclusions follow with equal steps.

First and most conspicuous of all stands the fact that the few engagements have been great smashers of theories as well as of cruisers and torpedo-boats. By the experienced, practical commander, as well as the theoretic strategist, war at the close of the Nineteenth Century has been pictured as a cold, scientific, unimpassioned affair, between highly refined instruments of destruction manipulated by men whose personal equation, beyond the simple qualification inherent in trained mechanics, did not enter into the problem. Dash and daring, endurance and pluck, courage and self-possession, were no longer factors of importance. The whole question was to hinge upon the long range, deadly accuracy, explosive powder and rapidity of action of the engines of war. And yet every aggressive movement of this war, whether on land or on the sea, has set these theorists at naught. The well-considered audacity and initiative of Dewey's attack at Manila was the determining factor in securing at so little cost the fruits of that brilliant victory. And what shall be said of the personnel, the steady self-possession, the nerve and daring which characterized the rank and file, officers and men, in the heroic dash upon the enemy's lines before Santiago? No superiority of equipment (for the Mauser rifle is as deadly a weapon as any in the hands of the American forces), not superiority of position (for that was with the other side), but the moral and physical qualities of the men who were behind the bayonets carried

the heights and won the day. Intelligence and moral force in the individual soldier is after all, even at the close of the Nineteenth Century, the true foundation of an army's greatness.

This is the more gratifying to those who are interested in the progress of civilization in that it demonstrates that a long period of peace does not sap the patriotism nor diminish the courage of a peace loving commercial people and that those qualities of character and mind which win success in the quiet walks of life are equally efficacious upon the battlefield.

THE BACTERIAL TOXINS.

THE meaning of surgical bacteriology in the clinical and therapeutic significance of the term would be much better expressed, for all practical purposes, by the term "surgical toxicology." By this it is meant that in the pyogenic and specific infectious diseases, the real source of danger and the real damage to the system, locally and remotely, is not the bacteria themselves but the products of the bacteria. The pathogenic bacteria gain entrance to the system because of a *locus minoris resistens*, and are enabled to invade new tissues, not because of a power on the part of the micro-organism itself to enter or kill healthy tissue, but because the chemical toxins or toxalbumins produced by the bacteria first prepare the way by lowering the vitality and thereby the resisting power of certain cells. A type of degeneration, a cloudy swelling, is produced and the bacteria may invade the tissues as rapidly as these poisonous substances have destroyed their resisting power. By their action in the walls of the blood-vessels a condition of inflammation is produced with a pouring out of white blood-cells and serum to further impair the vitality of the tissues. On the other hand it is the toxin that, from the very beginning of the process, osmoses into the blood stream as a crystalloid chemical substance and is carried to the thermogenic center to produce fever. If the bacterial growth is active and large amounts of the bacterial poisons are produced the system will be overwhelmed by the dose; cloudy swelling will be produced in the heart, liver, and kidneys, and the heart will be rapid, and the urine scanty and albuminous. The poison in the blood impairs the red blood-corpuscles and the patient is pale and anemic. Finally the patient dies because the heart can hold out no longer under the poisoning which is as definite and clear as the poisoning by arsenic, phosphorus or any other of the chemical substances that are poisonous to the body.

It is apparent that this chemical product, termed a toxalbumin, is the element of danger to the individual, and it is equally apparent that the clinical symptoms presented by such a patient are to be traced to the toxalbumin as well. The local inflammation, the fever, the rapid and feeble heart, the increased respiration, the anemia and various functional disorders are all dependent upon cell-degeneration in these organs or centers. Let us turn to the treatment of an infection. The one object of septic surgery is to obtain good drainage and the success of the treatment will depend upon the efficiency of such drainage. For this purpose free incisions are made to liberate the secretions laden with toxalbumins and bacteria and an effort is made to conduct them by means of drainage methods into our dressings instead of the blood; continuous irrigation or submersion are established in order that the chemical crystalloid substances may *diffuse* externally; and it is for a similar reason that the toxin-laden blood is sometimes removed from the veins and its place supplied by normal salt solution in order that we may remove mechanically a portion of the dose. The medication in the case is entirely confined to stimulation by alcohol, strychnin, digitalis, etc., to counteract the effect of the poison.

The bacteria themselves, although recognized as the remote and original cause, are playing a very small part in this scene. Most of us do not remember this often enough in conducting our surgical cases of infection. As has been said before, the term surgical toxicology expresses to our minds more exactly the cause of the symptoms that are present and at the same time gives us a properly directed treatment.

ECHOES AND NEWS.

The Northern Tri-State Medical Association.—The next annual meeting of this Association will be held at Elkhart, Ind., Tuesday, July 19, 1898. Hal C. Wyman, M.D., is President and H. D. Wood, M.D., Secretary.

Nurses for the Red Cross.—The Red Cross Society announces that it will consider the applications of none but trained nurses. Many unprofessional women apply for

positions as assistants, but they are not available for the purposes of the Society.

Death from Trichinosis.—Six members of a family named Von Zastrow, living near Binghampton, N. Y., died recently from trichinosis. The disease, as so frequently happens, was diagnosed as typhoid fever, and not till an autopsy was made upon the last victim was the exact condition known.

A Noted Morphin Fiend.—A case of chronic morphin poisoning was recently treated at Bellevue Hospital which surpasses all records in the amount of the drug which was daily consumed. The victim is a druggist and for three days previous to admission to the Hospital had been taking daily sixty grains of the sulphate of morphin.

The Hospital Train in Collision.—On Sunday night last the hospital train, while bearing a load of wounded soldiers to Fort McPherson, near Atlanta, Ga., met with a rear-end collision. The private car attached was demolished, but no lives were lost. Later the train continued its journey without further inconvenience to its passengers.

Vaccination in England.—The bill now before Parliament providing for compulsory vaccination is meeting with persistent opposition. Already ten pages of amendments have been offered and the antivaccinationists are doing their best in every way to discredit the measure. The profession, which now has a strong representation in Parliament, is doing what it can to sustain the bill.

Yellow Fever Promptly Suppressed.—The Marine Hospital Service announced July 9, 1898, that as far as is known there is not a single case of yellow fever in the United States. The total number of cases in the recent invasion at McHenry, Miss., was twenty-four. The last patient was discharged July 8th. There are no other cases under treatment and no suspicious ones under observation.

Blood Charts.—The clinical examination of the blood has been found to be of so great diagnostic and therapeutic importance that it is rapidly becoming a part of the routine examination of patients. The preservation of such records has been simplified by Dr. J. C. DaCosta, Jr., of Philadelphia, who has devised a systematic chart for notes of blood examinations. These charts are published by the J. B. Lippincott Co.

New Quarters for the New York Department of Charities.—Commissioner of Charities Keller, the deputies and the clerical force of the Charities Department, as well as the outdoor poor department, have moved from their old quarters at Third Avenue and Eleventh Street, into the new building, which has just been completed, at the foot of East Twenty-sixth Street. The new building, which was commenced under Mayor Strong, cost $60,000.

Measles in the Tropics.—Since the introduction of rubeola following the annexation of the Fiji Islands by the British in 1874, no epidemic is held in more dread by the natives of the Pacific islands. Owing to their ignorance of the dangers of the practice they could not be prevented from seeking relief from the cutaneous irritation by bathing in the nearest stream or surf. A mortality of more than thirty per cent. was the result. Quarantine laws of their ports emphasize the exclusion of measles above almost any other contagious disease.

Consolidation of the Buffalo Medical Schools.—Official announcement is made of the fact that the Niagara University Medical College and the Buffalo University Medical School have consolidated and have become one institution. It is announced by the *Buffalo Medical Journal* that this union is made in the interests of harmony and in accordance with the spirit of the age, which insists that there are too many medical colleges. What the name of the consolidated institution shall be is not stated, but as the Niagara Medical College is said in a measure to have sunk its identity, the natural inference is that that name will disappear.

Another Sneak-thief Victimizing New York Doctors.—A woman of slight build and medium height, dressed in mourning, calls to see the doctor who treated her husband and little girl two and one-half years ago. She is a glib talker and tells the servant that husband and girl are both dead. She states that the doctor wouldn't know her now for she was then quite stout; she lives out of town at present and is quite timid about coming to the city alone. She has a sore throat and coughs continually and asks the girl to kindly bring her a glass of ice-water. When she returns the would-be patient is gone. The doctor, when he returns, misses a sheet of postage-stamps from his desk drawers, an umbrella from the hat rack in the hall, etc., etc.

The Use of Intoxicating Beverages Restricted by General Miles.—Major-General Miles has issued a general order to the Army announcing that the history of other armies has demonstrated that in a hot climate, abstinence from the use of intoxicating drink is essential to continued health and efficiency; and enjoining the division commanders to restrict or entirely prohibit the sale of such beverages if the welfare of the troops or the interest of the service requires such action. For a general order emanating from the headquarters of the army upon this subject, a more positive statement would not have been out of place. No physiologic fact has been more thoroughly demonstrated than that the use of alcohol in climates representing the extremes of heat and cold, namely, in Arctic expeditions and in tropical campaigns, is not only not beneficial but positively harmful.

Typhoid Fever at Camp Alger.—Colonel A. C. Girard, chief surgeon of the Second Army corps, reports: "There have been only forty-one cases of typhoid fever since the camp was established on May 29th. Ten of these cases originated in the squadron of the New York cavalry. Four men arrived in camp with the disease, and six caught it while at farm-houses doing provost duty. Members of the Sixth Massachusetts now at the front contracted typhoid fever from well water at Falls Church depot while

doing provost duty. Other cases are isolated, and average about one to every regiment. The water in the wells of the camp grounds is absolutely pure, and has been tested by an analytical chemist from the Surgeon-General's Office in Washington. There are no cases of typhoid in camp now, as shown by the regimental surgeons' reports. As soon as a case is discovered the sufferer is sent to Fort Myer, and every precaution is taken to prevent the disease from spreading."

Antistreptococcic Serum.—The New York Board of Health has decided to put on public sale its antistreptococcic serum for the treatment of diseases caused by streptococcic infection. The success attained by the use of this product, not only in the laboratories of the Board of Health, but also in private practice, justifies this general recognition and distribution to the profession. The excellence of this serum is due largely to its freshness. No preservative fluid has yet been found which does not destroy the efficacy of antistreptococcic serum. The same is also true of tetanus serum. To make them of any value, therefore, a fresh supply of these preparations must be kept constantly on hand. The Board of Health is prepared to do this. The serum is put up in vials of two sizes, one of ten cubic centimeters and the other of twenty. They will be sold for one and two dollars each. The Board of Health also announces that it is prepared to make bacteriologic examinations, free of charge, of any suitable material sent from patients who have been or are to be treated with the serum.

American Medical Association and the "Spooner Bill."—Dr. U. O. B. Wingate desires to have a statement made regarding his understanding of the action of the American Medical Association upon the Spooner Bill, at its recent meeting in Denver. He presented resolutions approving of the Spooner Bill. "On motion the report was accepted. Another motion was made and duly seconded, to amend the last resolution by referring the same to the Board of Trustees, as it was necessary for all matters pertaining to appropriations to be referred to that Board. This motion to amend was carried. A motion was then made to adopt the report and resolutions as amended, and was carried. Thus, the Association adopted the report and resolutions with the exception of the last resolution, which was referred, for constitutional reasons, to the Board of Trustees." This explanation is evidently one which does not explain. The ruling of the presiding officer was certainly peculiar. A motion to adopt a report and resolutions burdened with an amendment referring to a Board of Trustees, which was carried, can hardly be construed, constitutionally, as giving the sanction of the Association to the original motion.

The Plague in Africa.—Professor Koch announced in Berlin on Thursday of last week the results of his investigations into the plague, which may arouse some apprehension. He declared that the view entertained ten years ago that the plague no longer threatens mankind must be abandoned. There are now no less than four plague centers, the last of which Professor Koch discovered in the Hinterland of German West Africa. Former outbreaks have been traced to Mesopotamia, where it has never entirely disappeared. But in China the plague is endemic, and its center is the province of Hunan. In Tibet is a second center. The latest outbreaks in China and India have had their origin there. The third center is on the west coast of Arabia, in the vicinity of Mecca. This center is of special importance in view of the pilgrims, but it is doubtful whether the plague is endemic in the neighborhood of Mecca. Nothing was known of any other plague centers until Professor Koch discovered a fourth in equatorial Africa. It was found that a devastating disease prevailed in Kissibia. Suspecting that it was the plague, Professor Koch proceeded from India to West Africa, and was able to identify the disease as bubonic plague.—*New York Sun.*

The British Medical Association.—The sixty-sixth annual meeting of the British Medical Association will be held at Edinburgh on Tuesday, Wednesday, Thursday, and Friday, July 26, 27, 28, and 29, 1898. The meeting will be presided over by Sir Thomas Granger Stewart, Professor of the Practice of Medicine and Clinical Medicine in the University of Edinburgh. The address in medicine will be delivered by Thomas Richard Fraser, Professor of Materia Medica in the University of Edinburgh, the address in surgery by Thomas Annandale, Surgeon to the Edinburgh Royal Infirmary, and the address in sociological medicine by Sir John Batty Tuke, Lecturer on Insanity in the Royal College, Edinburgh. Edinburgh has been long celebrated as one of the leading centers of medical education of the world. It is twenty-three years since the association last met in that city, and it is with no little interest that the members of the Association and its guests will note the substantial evidence afforded by new buildings, new organizations, and increased opportunities that Edinburgh is still keeping abreast of the times in all that goes to make up a great educational center. American talent will probably not be so much in evidence as at the Montreal meeting last year, but it is the intent of a goodly number of our representative men to be in attendance.

CORRESPONDENCE.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

THE BERLIN DOCTOR'S CLUB—PROFESSOR KOCH ON MALARIA AND SOME CIRCUMSTANCES IN THE CASE—EYE DISEASES IN SPAIN—PERNICIOUS ANEMIA AND ATROPHY OF THE GLANDS OF THE INTESTINAL TRACT.

BERLIN, July 3, 1898.

THE Doctor's Club of Berlin celebrated the formal opening of its club quarters on June 18th. A number of invited guests were present on the occasion, and with nearly 400 members a very pleasant evening was passed. When the club project was first hinted at it found a great many objectors, and there were ominous headshakings as to the political, university, and personal interests that would inevitably keep such an institution from being a

success. But thanks to the executive ability of Professor Lassar, whose management of the Lepra Conference showed foreigners the magnificent faculty for organization that Germans had long known him to possess, the new club promises to be a lasting and influential institution. Professor König, who occupies the Chair of Surgery at the University, said publicly during the evening that there was every reason to think that the new club, if it absolutely adhered to its avowed purpose of bringing the doctors together for social purposes only, would be able to do a great deal to obviate the differences and unpleasantnesses which the intense competition of a large city had inevitably brought into the profession. The general impression seemed to be that the club will accomplish this much-to-be-desired object—the lessening of what the Germans call *uncollegialität*—uncolleagueality, a very expressive and specific term for our indefinite euphemism unprofessional conduct. Such a desideratum is more and more making itself felt all over the world, and the German attempt at cutting of the Gordian knot of the difficulty by social organization cannot but be watched with sympathetic interest.

It is interesting to note that within this last month the announcement has been made that the medical men of Paris also have begun the organization of a club. Their avowed purpose, besides the benefit of the profession at home, is the proper welcoming of foreigners, especially for the International Congress in 1900.

Professor Koch is to talk in the near future before the *Deutsche Gesellschafft für Oeffentliche Gesundheitspflege* (society for the care of public health) on tropical hygiene. The exact date has not yet been announced. Some of his views on malaria, the doubt thrown on the existence of the remittent form of malaria, the non-malarial character of the hematuria which occurs during the course of the disease, the absolute prophylaxis afforded by quinin, and the tendency of the disease to be self-limited, were a source of considerable surprise to medical men generally. Perhaps some considerations of the circumstances under which they were expressed may help to the comprehension of the significance that is to be attached to them from a scientific standpoint. With the present interest in Germany generally, and especially on the part of the Imperial Government itself, in the colonization of South Africa, it was scarcely to be expected that very discouraging views as to the present status of the great scourge of that country, malaria, should be expressed before the German Colonial Society. Not that the observations have not their value but the opinions founded on them were bound to be modified by the thought of the importance of certain conclusions if they were true.

German colonization has never been a decided success. An American writer goes so far as to say that it has always been an utter failure and always will continue to be so, owing to the inadaptability of Germans generally to changes of climate, but this is evidently an exaggeration.

Of the Emperor's present *Welt politik*, or political policy, meant to give Germany a place in the world's politics everywhere, colonization, especially in the East and in Africa, is a favorite scheme. That under such circumstances even a great scientist should see things a little as he would like them to be and that the wish to lessen the evils of malaria should give rise to the thoughts, first that it is not as serious as most other observers have pictured it, and secondly, that the possibility of its complete eradication or at least modification by immunization is not distant, would be extremely natural. These considerations seem not without their value in the appreciation of Koch's recent views as to malaria, though of course his publication of them in a formally scientific communication must be awaited before serious criticism of them can be indulged in. Koch's closeness to the government once before, especially to its present head, who has some of the impetuosity of youth, not tempered by the judicial state of mind that comes from scientific learning, put him in a false position and led to the raising of hopes that were destined to sad disappointment. After that lesson there is all the more probability that this cannot have happened again and that Koch's views on malaria when given to the scientific world will be found to represent some really new ideas on an old, old subject.

A recent communication before the Berlin Ophthalmological Society of Professor Hirschberg, the well-known ophthalmologist, on blindness in Spain, seems of more than passing interest. It contains practically the substance of his paper before the International Congress of Hygiene at Madrid in April. A trip through Spain some years ago called his attention to the large number of blind beggars that he met in the cities. This led him to investigate the subject of blindness in the country. To his surprise the only official statistics he could find on the subject, those of the Government census of 1860, gave the number of blind to the 10,000 of population as only 11. As England, France, and Germany, have 8 or 9 blind to the 10,000 inhabitants this seemed in utter discord with what was to be seen. Further investigation showed that travelers ever since the beginning of the century had been remarking the number of blind to be met with. Recently the Spanish doctors themselves have been waking up to the condition of affairs, and so it has all come out. Like everything else done by Spanish government officials the statistics, because of official negligence, are absolutely of no worth, and are the result of most carelessly gathered information. Meantime eye diseases have been spreading alarmingly. Hirschberg says he has never seen such marked phthisis bulbi, or so many cases of it as he met incidentally in Spain. Even among well-dressed people it is quite common to see individuals who have lost one eye, and such people with both eyes lost are not a rarity. Even in the halls of the Congress itself they were to be seen. Hirschberg, whose paper at the Madrid Congress was in Spanish in order to call Spanish attention to the subject, sounded a note of alarm as to the neglect manifested in such serious eye diseases as purulent ophthalmia neonatorum and trachoma, and demanded for the protection of the people themselves and of other countries more general medical attention to eye diseases.

A recent graduation thesis at the University of Berlin on "The Changes in the Stomach and Intestines in Pernicious

Anemia," by Dr. Max Koch, contains a complete review of the literature of this interesting subject to date, besides the results of original work in Virchow's laboratory. Though all of the patient's examined had died of exhaustion from the pernicious anemia itself, *i.e.*, without intercurrent disease, the atrophy of the glands of the stomach and intestines were found at very varying stages of involution, in some far advanced, in others only just begun, so that the essential connection between the blood disease and the atrophic process is evidently an indirect one. This is only a confirmation, but from a new point of view, of the opinion now so general that makes the atrophy of gastro-intestinal mucous membrane secondary to the anemic condition. Though faithfully looking for them Dr. Koch was not able to find the corpora amylaceæ which have been found in these atrophic conditions in the intestinal mucous membranes, while they occur frequently in the gastric mucous membranes, an observation that if substantiated may furnish material for the explanation of the origin of these pathological mysteries, the amyloid bodies found in the central nervous system, and prostate in the old, and in the remains of hemorrhagic infarcts of the lungs in patients of all ages.

TRANSACTIONS OF FOREIGN SOCIETIES

London.

URACHAL CYSTS—INFLUENCE ON GOUT OF THE MINERAL CONSTITUENTS OF VARIOUS VEGETABLES—CANCER OF THE BODY OF THE UTERUS—REPORT OF THE COMMITTEE APPOINTED TO INQUIRE INTO THE CLINICAL VALUE OF DIPHTHERIA ANTITOXIN—FIBROMYOMA OF THE UTERUS UNDER TWENTY-FIVE YEARS OF AGE—ANTEFLEXION OF THE UTERUS AND DYSMENORRHEA.

AT the Royal Medical and Chirurgical Society, May 24th, DORAN read a paper on "Urachal and So-called Allantoid Cysts." It was long since shown that in most human subjects the urachal canal is patulous to a certain extent, and cystic dilatations of this canal are by no means uncommon. If the posterior wall of such a cyst can be dissected free from the peritoneum, the cyst should be removed *in toto*. Frequently this is impossible, and in such cases the cyst should be freely incised and drained. In every instance, the relations of the cyst to the peritoneum and abdominal viscera, including the bladder, should be accurately determined. The bladder may be entirely separate from the cyst, or it may communicate with it through a small opening. Such an opening into the bladder should be closed by suture. Doran read notes of a case in which he had evacuated and drained a urachal cyst containing a pint or more of a brown glairy fluid. The patient recovered.

At the meeting of June 14th, LUFF read a paper on the "Influence on Gout of the Mineral Constituents of Various Vegetables." He carried on a long series of experiments to determine, (*a*) the effects of the mineral constituents of various vegetables on the solubility of sodium urate at the temperature of the body, and therefore presumably on the uratic deposits; and (*b*) the influence, if any, exerted by these constituents in retarding the conversion of the sodium quadriurate contained in the fluids of the body into biurate. Obviously the elucidation of these points will have a direct bearing on the treatment of gout. The vegetables employed were spinach, Brussels sprouts, potatoes, asparagus, Savoy cabbage, French beans, lettuce, beet, winter cabbage, celery, turnip tops, turnip, carrot, cauliflower, sea-kale, and green peas. It appears that 0.05 per cent. or more of the mineral constituents of nearly all of the vegetables exerts an influence on the solubility of sodium urate. Green peas were, however, absolutely inert. Curiously enough in these experiments, modern science was only confirming the practice of the ancients, who gave ashes of vegetable matter for the gout. Not all the vegetables given were, however, capable of delaying the conversion of the quadriurate into the biurate, but from the results of his experiments certain vegetables stand out as preeminently fitted to be eaten in gout. These are spinach, Brussels sprouts, French beans, Savoy and winter cabbage, turnip tops, turnips, and celery. Attempts to substitute for the vegetables themselves an artificial mixture of those substances which are found in their ashes by analysis, have so far proved unsuccessful. The artificial ash corresponding to the natural ash of spinach was found to have a *deterrent* effect upon the solubility of the sodium biurate. Whether a mixture of the natural ashes of different vegetables can be gived in place of the vegetables themselves has not yet been ascertained, and Luff is still working upon that problem.

At the Harveian Society, May 12th, HANDFIELD-JONES read a paper on "Cancer of the Body of the Uterus." Cases were quoted to show the unreliability of a diagnosis of malignant or benign growths made from scrapings of the uterus. Clinical signs are of much more value in determining the necessity for operative measures. Especial stress is to be laid on a rapid increase in size of the organ, although cancer of the body of the uterus is much less malignant than that of the cervix, and the disease may run a very long course. It is by no means limited to nulliparous women, but is almost equally common in those who have borne children. In the discussion which followed the reading of this paper, several members expressed their conviction that the microscopical examination of uterine scrapings is of little value.

ROUTH emphasized the importance of metrorrhagia at the menopause, which he considered a very serious symptom. The best guide to a correct diagnosis, is the finger *in utero*. He advocated the removal of any uterus after the menopause, which after curetting, continued to bleed and to increase in size.

At the Clinical Society, May 27th, CHURCH read the "Report of the Committee Appointed to Inquire into the Clinical Value of Diphtheria Antitoxin." The report was based upon the analysis of 633 cases. Of the patients who presented symptoms of laryngeal affection, nearly one-half escaped the operation of tracheotomy, a much larger proportion than is usually the case with diphtheria treated in other ways. Tracheotomy was performed seventy-five times, but only in two cases after the elapse of twenty-four hours from the first injection. The mortality

after tracheotomy was 36 per cent., as opposed to a mortality of 71.6 per cent. of a series of cases collected from general hospitals before the introduction of treatment by antitoxin. In the first five years of life the decrease in mortality after tracheotomy is most marked.

The total mortality in the 633 cases was 19.5 per cent., as opposed to 29.6 per cent. in the non-antitoxin control series. Not only was the mortality in the antitoxin series much less than in the other series, but the duration of life in the fatal cases was greater, a fact which has an important bearing on the development of paralyses. The closest investigation of the cases failed to reveal any connection between the use of antitoxin and the paralytic symptoms, neither as to the amount injected, nor as to the period of the disease at which injections were commenced. Some form of rash followed in about one-third of the cases in which antitoxin was used. Most of these rashes were erythematous or urticarial in character, the former type predominating. These had no bearing on the outcome of the disease. Pains in the joints due apparently to the serum were observed in a few cases of the antitoxin series. The percentage of deaths with suppression of urine was the same in both series. The general result of the inquiry showed that in the patients treated with antitoxin not only was the mortality notably lessened, but the duration of life was also prolonged. The injection of antitoxin may produce rashes, joint pains, and fever; with these exceptions no prejudicial action has been observed to follow in the series of cases investigated, even after the use of a very large quantity of the serum.

At the Obstetrical Society, June 1st, SPENCER read a paper on "Cases of Fibromyoma of the Uterus Occurring in Women under Twenty-five Years of Age." A brief abstract was given of forty recorded cases, and of two operated upon by himself. His conclusion was that uterine fibromyoma is rare before the twenty-fifth year, and is very rare before the age of twenty has been reached. There is no record of its occurrence before puberty.

HORROCKS upheld the reader in his views as to the rarity of fibromyomata in early life. They are also much commoner in single women than in married women, and in women who have never been pregnant than in those who have. Moreover, the tumors begin to atrophy as a rule after the climacteric. These facts and the further fact that they do not occur before puberty prove that they are in some way associated with active menstrual life.

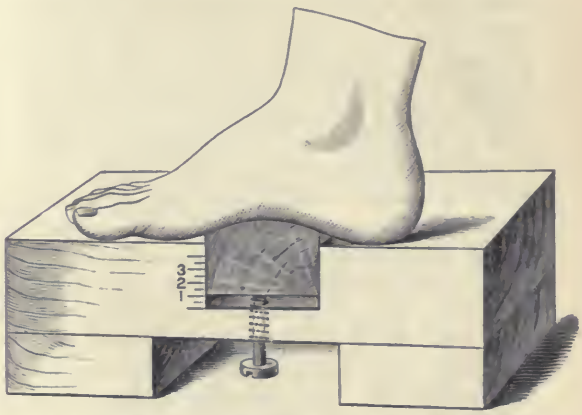
At the British Gynecological Society, June 9th, BANTOCK discussed the subject of "Dysmenorrhea in Anteflexion of the Uterus." He recognized three typical forms of anteflexion as follows: (1) That in which the body and cervix are both bent forward; (2) that in which the cervix is alone bent forward, the body remaining in fairly normal position; and (3) that in which the anteflexed uterus lies on its back in the bottom of Douglas' pouch. The bend *per se* is not the cause of the pain. It is only when the resultant congestion and thickening of the mucous membrane, which follows the obstruction to blood-flow has become well established that the pain is prominent. The character of the discharged blood clearly shows that there is an obstruction to its flow, as does the enlargement of the cavity of the uterus. For this condition there are only three rational methods of treatment: (1) Division of the cervix; (2) the stem-pessary; (3) dilatation. No operation upon the external os can avail when the condition to be remedied has its seat at the internal os. No vaginal pessary is of service in the treatment of anteflexion. The best method of dilatation is that by graduated bougies. It generally requires to be repeated at intervals.

NEW INSTRUMENT.

TO DETERMINE THE THICKNESS OF THE PAD USED IN PES PLANUS.

BY DAVID TRUMBULL MARSHALL, M.D.,
OF NEW YORK.

THE accompanying sketch shows an arrangement for determining the thickness of the pad used in the treatment of pes planus. The apparatus consists of a block of wood having in its center a recess or groove in which slides a block. The block fits accurately into the groove



and may be raised or lowered by means of a thumb-screw. The foot is placed upon the block, the patient resting his entire weight upon it. The movable block is raised by means of the thumb-screw until the arch of the foot is comfortably supported. The height of the block is read off on a scale at the side, and the pad then made without the tedious trying and building that is necessary in the ordinary method.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held May 3, 1898.

DR. FREDERICK PETERSON, the new president of the Society, delivered an address, entitled

NEW PATHS IN PSYCHIATRY.

He said that a recent writer had described psychiatry as the new Prometheus which would wrest from Nature the secret of thought. The anatomist, the cytologist, the chemist, the embryologist, the pathologist, and in-

numerable other specialists are now engaged in different lines of research connected with the workings of the human body. Of the numerous pathways extending out before us into dimly lighted regions, one of the most intricate is that of physiologic and pathologic chemistry. The roads of normal and pathologic histology and cytology are more traveled. At least one of these roadways leading into the realm of the mind, and which any one in the Society might follow with profit, is that opened up by careful clinical study of organic diseases of the brain, in accordance with modern methods from the standpoint of psychology. He believed it to be of the greatest importance to study the quality, intensity, and tone of sensations, the contents, distinctness and energy of ideas, the evolution, durability, and associations of ideas, disorders of the affected life, such as depression, exaltation, apathy, and irritability, and the disorders of the idea-associations as regards memory, attention, rate of flow, coherence, ethical feeling, etc. Our studies of aphasia in the past had been remarkably deficient as regards the psychic side. Doubtless the new psychological theories would, in turn, give place to better ones, but there is a certain charm in sifting the psychical processes down to stimulus, sensation, idea-association, and movement. It becomes a delight to study the disorders of sensation, disturbance of the memory pictures, derangement of the idea and judgment-associations, and the influence of these disorders on the actions and conduct of the individual. The psychological laboratories attached to some of our universities, dealing as they do with the normal mind, cannot hope to accomplish as much as similar foundations attached to asylums for the insane and clinics for nervous diseases, in which a large mass of morbid material is collected. The great city of New York, with all its wealth and benevolence, might well lead the New World in the establishment of a psychiatric clinic, fully equipped for all modern investigation in this field. A psychopathic hospital would prove a boon in many ways, not the least of which would be the benefit to the insane now gathered into a single pavilion attached to one of the hospitals merely for distribution to various asylums, to the students of medicine, and to those interested in solving some of the riddles of the mind.

SUTURE OF THE MEDIAN NERVE.

DR. B. FARQUHAR CURTIS presented a young woman who, last September, received a small punctured wound of the right wrist. Following it there was anesthesia of the forefinger, and, to a less extent, of the thumb and middle finger, but without any marked paralysis. The area of anesthesia was not quite typical of that observed after complete division of the median nerve, because the ulnar side of the middle finger was not involved. The operation had been performed a week before, and on exposing the nerve it had been found that it had been completely divided in spite of the atypical area of anesthesia. On cutting off the bulbous ends an interval of about one inch was left between the ends of the nerve. Both ends were forcibly stretched and apposed, and the hand kept in a flexed position by a suitable splint. Two or three catgut sutures were passed, not merely through the sheath, but through the nerve itself. Instead of cutting away the bulbous ends entirely, the fibrous part of the sheath was preserved and used as a sort of flap for the reinforcement of the suture. The anesthesia had been so complete before the operation that she had repeatedly burned the ends of the fingers.

TRAUMATIC ULNAR NEURITIS—TRANSPLANTATION OF THE NERVE.

DR. CURTIS also presented a woman, twenty-eight years of age, who had been doing a good deal of writing with a pen. In childhood she had received a fracture of both condyles of the right elbow. As a result of this the ulnar nerve lay upon an exposed surface instead of in the groove. For two or three years there had been increasing numbness and pain. Dr. Dana had seen the case, and made a diagnosis of neuritis. Dr. Curtis exposed the nerve by a curved incision and flap. The nerve was found to be thickened for a distance of about an inch and a half, and to about twice its normal diameter. On incision through the sheath, there seemed to be a general increase of the fibrous tissue of the nerve. The nerve was split and stretched gently, and then removed from its exposed situation to a more protected part, *i. e.*, to the front of the elbow. The result had been surprisingly satisfactory, so that she had been enabled to resume her long hours of writing without discomfort. The speaker said that there had been some cases reported of dislocation of the ulnar nerve in which the nerve had been restored to its proper groove by operation. There had been no material change in the general appearance of the hand, except, perhaps, that it was a little more plump.

DR. SACHS said, regarding the maintenance of sensation in the ulnar half of the hand in the first case, that the areas of sensation pertaining to the two nerves are so irregular that one cannot predict with any certainty as to the result in any given case. The result in both patients presented was certainly very good.

TREPHINING FOR EPILEPSY.

DR. CURTIS then exhibited a recent case of trephining in epilepsy, with a view to illustrating the technic of the general operation of craniotomy with a bone flap. The patient, an Italian, twenty-five years of age, had had epilepsy quite severely, but the details of the previous history were not in his possession at present. There were no localizing symptoms, but there was a scar on the right side of the head, and at Dr. Hammond's suggestion an exploratory operation was performed last March. As there was no definite localization, a large opening was required. This was made by the osteoplastic method, using the wire saw. Four small trephine openings were rapidly made, and then a flat director of German silver was passed between the skull and the dura from one opening to the other. Through this an eyed probe armed with a string could be passed. The string served to carry the wire saw. The latter is nothing but a piece of piano-wire, having a screw-thread cut upon it. It is operated like a chain-saw, and cuts very rapidly. The advantage over the electric saw is that it eliminates

the uncertainties connected with the use of a battery. The disadvantage of having to put a guard underneath is one which is shared by all the other methods of this nature. As the saws are very cheap, a new one can be used for each patient. The saw was used on the three sides, and the remainder of the flap broken away. Fully one-third of the brain was exposed in this way. It seemed to him much easier to make these large openings and work through them than through the smaller trephine apertures. The cut with the saw is made obliquely, so that immediately afterward the bone can be replaced and will rest firmly in place. In this case, some atrophy of the cortex and of the underlying parts was found.

Dr. Curtis then reported the cases of two other patients who had been operated upon previously, and who had failed to present themselves at this meeting for inspection. The first case was that of a married woman, thirty years of age, who, as a result of a fall, had severely injured her right arm. She did not have any epileptic fits, however, until six years before coming under Dr. Dana's observation. Shortly before that time they had become very frequent and severe. In other respects she appeared to be healthy. The attacks always began in the left foot and spread up the leg; then they attacked the arm and spread to the body. She frequently had a complete, general, and typical epileptic attack, with loss of consciousness. There was no paralysis and no optic neuritis. She would have as many as a dozen attacks in one night. The speaker said that at the operation he had made an opening, two inches in diameter, over the fissure of Rolando. On testing the centers with a strong current of electricity, an intense general convulsion had been provoked. This began in the left leg, and the pulse becoming very feeble, the wound was closed temporarily. It was worthy of note that the fits continued nothwithstanding the relief of pressure afforded by the removal of the bone. A week after this operation the wound was reopened, and a flap of dura was turned back. The vessels surrounding the motor-centers were ligated, and then the cortex on both sides of the fissure of Rolando and the region of the arm and leg centers were excised. Some adhesions to the pia mater were encountered and separated. There was some rise of temperature, but no other sign of inflammation after the operation. The patient was completely paralyzed in the left arm and leg, and had a few fits during the first week, and her whole demeanor underwent a marked change. After a time the mental depression passed off, and when she left the hospital she was in good spirits. She took the bromids during her stay in the hospital, but discontinued them afterward. Motion in the arm and leg began six weeks after operation, and in six months she had complete power in both extremities. Eighteen months after operation he had examined her. She had gained twenty or thirty pounds in weight, and had entirely recovered the use of the hand and leg. She no longer had fits, and was in the best of health, her former cheerfulness and mental activity having been restored. Slight headache and indisposition to meet people at certain times were the only remnants of the old trouble. There was a considerable depression of the scalp over the aperture.

The second case was one of hemorrhagic cyst of the brain, with epilepsy, in which recovery followed the operation of trephining. The patient was a Russian boy, thirteen years of age, who was admitted to the Post-Graduate Hospital on June 11, 1896. Fourteen months previously he had had a cerebral hemorrhage, with left hemiplegia, and for about a year he had suffered from epileptic fits. There was no special localization, but he was guided to the situation by the limited paralysis on the opposite side of the body. In this case, the operation was about the same as in the other. The aperture made was about two inches in diameter over the motor region. The dura was opened, and when the circulation became feeble the brain appeared unusually blanched and soft. Further exploration revealed a cystic cavity immediately underneath the cortex. Here the cortical substance of the brain was very much thickened by fibrous tissue. The cavity extended backward into the posterior lobe and forward for three or four inches. The cyst contained clear serum, but there was no tension in the cyst. The cyst was closed by catgut sutures, as the brain tissue was quite fibrous, and permitted such a method to be used. The operation was done on July 4th. On October 25th there were seven convulsions during twenty-four hours. On the following day a large aspirating-needle was plunged into the cyst, and five or six grams removed. He remained free from convulsions until February 18, 1897, when it became necessary to repeat the aspiration. Up to last January he had remained free from convulsions under the use of the bromids.

DR. W. M. LESZYNSKY said that he had seen this boy about one week ago. Although before operation the bromids had had absolutely no effect, since the last aspiration of the cyst the boy had been comparatively well. He had been taking 30 grains of bromid three times a day, and now had only an occasional slight attack, limited to the paralyzed side—about one in three weeks—and his mental condition had improved. He had reported the case to the American Neurological Society last year. Even in such apparently hopeless cases some benefit seemed to follow surgical interference. He had suggested an exploratory operation in view of the limited character of the paralysis.

DR. C. L. DANA said he desired to emphasize the remarkable success achieved in the case which had been under his observation, and which was one of true, classical Jacksonian epilepsy, without any discoverable gross lesion of the brain. Dr. Collins and he had made a microscopic examination of the excised part, and had found marked degenerative changes in the cells. Dr. Collins had published in *Brain* the results of this study. Dr. Dana said he had no doubt that the case, if left alone, would have developed into one of ordinary epilepsy.

DR. SACHS said that one great obstacle to the successful performance of these operations has always been the difficulty of obtaining a suitable saw. The instrument just exhibited seemed to be a great improvement on former instruments. Most of the neurologists and sur-

geons seemed now agreed upon the advisability of using a large flap. He thought a careful record should be made of every case of this kind in which a good result has been obtained, because the whole subject of the surgical treatment of epilepsy had lately received another serious blow from Bergmann. Certainly, a sufficient number of patients have been relieved by operation to warrant a selection of such cases as seem suitable for operation, particularly those in which the interval between the development of the epilepsy and the operation is not very long. The fact that in the case just reported the interval had been six years made the good result all the more remarkable.

DR. J. ARTHUR BOOTH said that it was common for patients to go without attacks for two or three years under the bromid treatment, and without surgical interference; hence, these persons should not be considered cured until at least four or five years have elapsed.

DR. PETERSON also thought it extremely important that careful records of these cases should be kept for a long time after operation. At least four years should elapse without an attack before a patient should be considered cured.

DR. CURTIS said he had not intended to bring up the general subject of the surgical treatment of epilepsy at this time. He thought the surgeon should be willing to operate upon a good many of these patients, but two classes should be carefully distinguished, *viz.*: (1) Cases like the ones just reported, in which there is a localization of the epilepsy, and (2) cases like that of the Italian just presented, whose future is hopeless and whose history is very vague. For the sake of the few who might be benefited, it seemed to him justifiable to operate. The operation certainly causes a temporary amelioration of the symptoms, and this repays the patient for the slight risk incurred by submitting to the operation. In cases requiring an extensive and dangerous operation the probable benefit is correspondingly great. He was not enthusiastic about this kind of work, and did not speak of the patients as "cured," but it was certainly worth while to place the cases on record. At present, an exploratory operation seemed to him justifiable and desirable.

REVIEWS.

YEAR-BOOK OF TREATMENT FOR 1898. A Critical Review for Practitioners of Medicine and Surgery. Philadelphia and New York: Lea Bros. & Co., 1898.

THE fourteenth annual volume of the "Year-Book of Treatment" lies before us. Like its predecessors, it contains the correlated knowledge on the treatment of diseases in the various specialties of medicine in complete and compact form.

Year-Books have taken a permanent place in medical literature, and this one has always occupied a unique position for its completeness, the choice of its selections, and its excellent literary form. A few changes have been made in the list of authors in the present volume. The work is to be most cordially recommended for general use.

AIDS TO ASEPTIC TECHNIQUE. By A. D. WHITING, M.D., Assistant Surgeon to the German Hospital, Philadelphia. Philadelphia: J. B. Lippincott Co., 1898.

THIS little work is intended to be of assistance to nurses and surgical assistants who are obliged to prepare aseptic materials for surgical operations. In the scope of its work the author has undertaken to establish the reasons for the procedures which he describes, and in most instances has done this admirably. His descriptions of the technic of the various methods employed in this work are modern and thorough. The work is a good one for those for whom it is intended, but almost too superficial for the surgeon. The few illustrations are well executed and the book is well made.

THERAPEUTIC HINTS.

For Dandruff.—

℞ Green soap . . . . . ℥ iii
Melt at low temperature and add:
Rectified alcohol . . . . ℥ iss
Glycerin . . . . . ʒ iiiss
Filter and dissolve in the filtrate:
β-naphthol . . . . . gr. xl.

M. Sig. To be used with water as a soap for the scalp.

For Obstinate Vomiting.—

℞ Tinct. iodi . . . . . gtt. x
Aq. dest. . . . . ℥ iv.

M. Sig. One tablespoonful in half a glass of sweetened water between meals.—*Steffen.*

Administration of Chaulmoogra Oil in Leprosy.—The following formula is recommended as enabling the drug to be taken and retained without difficulty:

℞ Ol. chaulmoograe . . *m.* xxx—*m.* lxxx
Ol. amygdal. dulc. . . ʒ ii—ʒ iiss
Acaciæ . . . . ʒ iv
Syr. aurant. cort. . . ℥ i.
Aq. laurocerasi . . *m.* lxxx
Lactis . . q.s.ad. ℥ iv.

M. Sig. To be taken in divided doses (four or five) during one day. A little whisky may be added if desired.—*Danlos.*

Lactophenin in Typhoid Fever.—It is the experience of Diaz of Palma that this drug will abate the fever and restlessness in typhoid fever without inducing the perspiration and exhaustion which may follow the use of antipyrin or phenacetin. He gives from forty-five to seventy-five grains in twenty-four hours and has never found it to cause gastro-intestinal irritation or other undesirable symptoms.

For Acute Gastro-enteritis in Infants.—

℞ Bismuthi subnitrat. . . . gr. xl
Tinct. opii camphorat. } aa . *m.* xlviii
Tinct. chamomilæ }
Glycerini . . . . . ʒ iiss
Ag. cinnamomi . . . . ℥ ii.

M. Sig. One teaspoonful every three hours.

ORIGINAL ARTICLES.

THE DIAGNOSIS AND TREATMENT OF EARLY TUBAL PREGNANCY.[1]

BY JOSEPH BRETTAUER, M.D.,
OF NEW YORK;
ADJUNCT GYNECOLOGIST TO MT. SINAI HOSPITAL.

THOUGH the subject of ectopic gestation has received a great deal of attention during the last few years, it is hardly necessary for me to apologize for bringing it before you. We need but to consider the gravity of the condition and its frequent fatal termination to find ample justification for reviewing the subject before a body of practising physicians, who, in the large majority of instances, are the first to see and advise in the emergencies which arise in this condition. To be able to meet these emergencies most advantageously it is of the first importance to recognize them. In order that we may prevent their occurrence, we must learn to diagnosticate an extra-uterine gestation before the alarming symptoms which sometimes accompany or follow it set in.

It is not my intention to go into an exhaustive study of the subject in its etiologic and pathologic aspects but rather to show how we can best meet these emergencies, as I have been taught by my own experience, gained through the clinical observation of thirty-four cases which it has been my good fortune to see within the past six years. The fact that I had occasion to see only four patients before any complicating or alarming symptoms had appeared would indicate that this condition in its inception causes only slight disturbances, scarcely enough to bring the patient to the physician's office. This I am sorry to say is quite true of a number of cases, and in such of course a serious accident may intervene before we have seen the patient. But the number of such cases is small compared to those in which the condition of affairs is not only not recognized but not even suspected. They are diagnosed as threatened or incomplete abortions, until sudden collapse makes the diagnosis clear. It is in these cases that we must learn to suspect the condition at once and either verify the suspicion by further observation or diagnose some other disturbance. It is intentionally that I use the word "suspicion" since it is in most cases impossible to diagnose an unruptured tubal pregnancy after a single examination. But once suspected we will be on the lookout and will carefully observe the patient.

As in no other pathologic condition I have learned in these cases to appreciate the value of a minute, carefully taken history and of a close study of the symptoms present. In all text-books, even in the most recent, we find "amenorrhea" mentioned as one of the cardinal symptoms of ectopic gestation. This is only partially correct and it is misleading, since it is not infrequent that there has been no cessation of menstruation; I would even go so far as to say that amenorrhea is the exception. But irregularities in menstruation or irregular uterine hemorrhages are in my experience not only the rule but are the very symptoms which lead these patients to seek advice. We hear that shortly after menstruation, say one or two weeks, a slight show was noticed; that it disappeared and after a few days reappeared; the time for the next period was marked either by a more profuse flow or by its entire absence. Or at the regular time of menstruation a scant discharge took place, stopped, and reappeared within a few days. Only rarely has it been my experience to find that "amenorrhea" has been present for one, two, or more months before this bloody discharge showed itself. These and some similar variations in the menstrual history are constant symptoms and to me always sufficient to call into consideration the possibility of tubal pregnancy. General and reflex symptoms of pregnancy may be present or not; they are more marked if the impregnation occurs in women who have been sterile for a number of years. These comprise a sense of fulness in the abdomen, swelling of the breasts, frequent micturition, and gastric disturbances. A certain feeling of heaviness in one or the other inguinal region which two of my patients felt but were unable to describe more closely, deserve mention, as it has been observed by others also.

These few subjective symptoms, together with the atypical or irregular bloody discharge should at once give rise to the suspicion of ectopic gestation. This suspicion, however, will at once be set at rest if on bimanual examination we find a normally pregnant or a pregnant retroverted uterus, both of which conditions will give rise to these symptoms if for some reason or other pregnancy has been disturbed and an abortive process has set in; and secondly (and this is far more important), if the uterine appendages are

[1] Read by invitation before the Monroe County, New York, Medical Society.

felt to be normal. Should we find, however, besides an enlarged and softened uterus a tumor of varying size to one side or behind it, the suspicion of ectopic gestation will rest on much firmer ground.

The typical characteristics of a pregnant tube differ widely from those evoked by any other possible condition. Laterally or behind the enlarged, slightly softened uterus, we feel a mass, varying in size from a large walnut to an orange, somewhat tender to the touch, movable, distinctly pulsating, imparting to the fingers a pseudo-fluctuating, boggy impression, and sometimes contracting during palpation. These symptoms together with the points already gained from a minute history are typical and decisive for an absolutely positive diagnosis. The expulsion from the uterus of a decidua *in toto* or in shreds at this stage is not a constant occurrence but is characteristic. In illustration I will give briefly the history of a case in which the diagnosis was made at this period and was verified by operation:

Mrs. M., thirty-eight years old, had had one child twelve years before, and four miscarriages since. On August 2, 1893, when I saw her first she said that her periods had been perfectly regular until July 15th, when after she had been two weeks overdue she had had a flow and had been treated for an abortion. Though she had expelled a membrane from the uterus she did not believe it to be an ovum for the sac was apparently an empty bag and judging from her former experience in this direction the membrane did not strike her as one containing a fetus. Because of a peculiar dragging sensation in her abdomen she consulted me. On close questioning I learned that though the regular menstruation had been suppressed she had had a slight show one week before the period was due. This, however, had only lasted a few hours and had not reappeared until three weeks later, when the flow started again and kept on varying in degree until the membrane above spoken of made its appearance. Such symptoms of pregnancy as nausea, a sense of fulness in the breast and slight pigmentation around the nipples were present. On bimanual examination a tumor of the size of an orange was felt to the right of the enlarged uterus. It had the characteristic features above described and at once the true state was manifest. The patient, a very intelligent woman, was not at all surprised when informed of the probable condition, consented to be operated on, but only wished a few days to arrange her business affairs, promising meanwhile to keep quiet and not exert herself physically. On account of severe cramp-like pains in the right iliac region she sent for me twenty-four hours later. Operation was now considered urgent and was accepted. The diagnosis proved to be correct; a still unruptured pregnant tube was removed which showed its peritoneal covering in some places already torn with slight bleeding from the underlying tissue.

Unfortunately, however, the conditions are only very rarely as clear and as distinct as in the case just narrated. Frequently we find patients of inferior intellect whose powers of observation are limited, who are unable to help us in elucidating a true and distinct history not only as to the present condition, but in regard to previous inflammatory processes as well. An examination is often made difficult by hyperesthesia, or by fat, or by contracted abdominal walls, which necessitates an anesthesic to enable us to explore the pelvis. Here too we may find a tumor, but may be unable to detect the classical features of a tubal pregnancy. We are then confronted with the task of making a differential diagnosis between various other possible conditions on the one hand and tubal pregnancy on the other. This is not only a difficult problem but sometimes one the solution of which is impossible. We have then to be satisfied with a mere probable diagnosis of ectopic gestation, as the outcome of our examination, painfully careful though it may have been.

We may exclude from the diagnosis normal pregnancy, still existing or interrupted, with coincident swelling of the uterine appendages, due either to cystic or inflammatory changes if, after repeated examinations, we find, for instance, that the mass has grown while the uterus appears either the same in size or even smaller. Pregnancy in a bicorned uterus may very easily be mistaken for an ectopic gestation, and can be excluded only by the most careful palpation of the pelvic contents under narcosis. This condition is, however, of too rare occurrence to play an important rôle in our diagnosis. Pregnancy in a retroverted uterus, with or without accompanying pathologic conditions of the tubes and ovaries, has in my experience always been easily distinguished from a tubal pregnancy. Only in a small number of cases will the uterine sound prove to be of any material use in our attempt to reach a conclusion. It helps us in doubtful cases to recognize positively the position of the uterus; it may prove the emptiness of the uterine cavity, but gives no hint as to a previous abortion. The microscopic examination of expelled shreds I consider of great importance when done by pathologists thoroughly familiar with the subject. It surely helps us in a given case to assert positively that a process of gestation has been established; sometimes under very favorable circumstances the microscopist may even be able to go farther in his assertion and state that the pregnancy has not been uterine.

The symptoms of tubal pregnancy will be much more distinct if the walls of the tube are unable to reach the degree of distention required by the growth of the ovum. The tube will either gradually tear or else it will make efforts to expel its contents through

its distal end into the peritoneal cavity. We are then told of pain extending over hours or sometimes days with but short intermissions. The character of these pains is not only severe but of such a nature that patients are less able to endure them than any other pains they are called upon to suffer. They begin usually in one inguinal region and not infrequently cause the patient to feel faint or even lose consciousness for a short time. On recovering nothing pointing to any serious disturbance is noticed until another attack occurs. These pains, caused by contraction of the tubal walls, are in my experience usually followed by the expulsion of pieces of decidua from the uterus. With the history of disturbed menstruation and the presence of a pelvic mass of appropriate size, these symptoms are sufficient to warrant a diagnosis of still unruptured tubal gestation.

Much easier is our task when we are called to see a patient at the time of or soon after rupture of the tube, or when a tubal abortion has occurred. Harmless and as little disturbing as the presence of an unruptured pregnant tube appears to be, just as alarming and distressing is the condition when rupture has taken place, or when the tube has expelled the ovum into the peritoneal cavity. We are told of a sudden attack of severe abdominal pain followed by a loss of consciousness. The patient herself shows all the signs of severe shock and acute anemia. The skin is pale and cold, the radial pulse if at all perceptible is small and rapid. The abdomen is slightly distended and extremely sensitive to the touch. The temperature is normal or even subnormal. By the vagina we get the impression of fulness in the pelvis without being able to feel a well defined tumor. Should the patient soon recover from this condition of collapse and the symptoms abate, it is often only a short interval before collapse again takes place. With the aid of a history of irregularities in menstruation we have now little difficulty in making a diagnosis of a ruptured tubal pregnancy though it is nearly impossible at this moment to distinguish a tubal abortion from rupture, since both accidents are principally characterized by the signs of severe and repeated hemorrhages. Although it may often be difficult to differentiate an ectopic gestation before its rupture from a pyosalpinx or an ovarian abscess, it is comparatively easy to do so after the rupture of either. In the latter instances the condition just described is based solely on shock, no active hemorrhage having taken place; in a few hours the signs of acute shock will have disappeared and are replaced by those of acute sepsis.

Luckily not all of these women die in consequence of tubal rupture or abortion. A number of them, I am glad to be able to say, quite a large number, recover from this most serious and apparently hopeless condition. The escaped blood coagulates and plugs the bleeding vessels by mere pressure. A peritoneal irritation caused by the sudden traumatism becomes a localized peritonitis and results in the shutting off of the coagulated blood from the free cavity and forms the so-called retro-uterine hematocele. As a rupture of the tube within the folds of the broad ligaments and consequent collection of blood extraperitoneally, is a rare occurrence, I refrain from going into the discussion of its clinical aspect and will content myself by saying that if it occurs, its symptoms are surely not so alarming and only seldom call for our interference. This is probably the reason that we so rarely have the opportunity to study this condition either on the operating- or the dissecting-table. In its recent state the retro-uterine hematocele is easily recognized, especially if the history gives any of the points already dwelt upon. The uterus is usually pushed forward, the mass fills the pouch of Douglas sometimes to such an extent that the posterior vaginal wall bulges very low down; while above the mass extends not infrequently beyond the brim of the pelvis. It appears soft, not fluctuating, immovable, and tender, As time passes this tumor of coagulated blood becomes tenser, harder, and very much smaller. The effused serum is absorbed and the clot begins to organize. The facility of recognizing the condition decreases with the length of time elapsed since its development. After months have passed the memory of the patient fails to reproduce the exact circumstances of the former illness, severe as it may have been. Irregularities in the menstrual flow, pains, and everything else which might lead us to the right path are forgotten, a hard mass in the pelvis is all we find, whose relation to the uterus and appendages we are unable to define minutely. While bearing in mind all the possible pathologic conditions we are now able to make our diagnosis only by way of exclusion, or may be able at most only to confine the number of possible conditions within small limits.

In most cases the expulsion of the ovum into the peritoneal cavity, be it through a ruptured tube or through the distal end of the tube, is not survived by the fetus. Occasionally, however, for some reason or other, rupture of the gestation-sac is not followed by the death of the fetus. In these cases with the lapse of time the diagnosis becomes less difficult. As such cases are not very frequent I shall give the history of the only one I have been able to observe:

Mrs. S., twenty-five years of age, had had one child four year before and three miscarriages, all at the

beginning of pregnancy. Menstruation regular, always more or less profuse. She had menstruated just three months before her admission to Mt. Sinai Hospital on August 11, 1894, but had noticed that the flow was decidedly less than usual. About ten days afterward a bloody discharge was seen only for a few hours or so. With the exception of slight general disturbances which the patient had experienced during each of her pregnancies she was perfectly well until three weeks before admission. Then on performing some household duties she was suddenly seized with a sharp, intense pain on her left side, which caused her to faint. A few hours afterward the pain had ceased and the patient felt well until another similar attack two days later. Within the next three weeks she had three more attacks, after each of which she had fainted, and was unable to move for some time afterward. Slight uterine flow had accompanied the first attack and had not ceased since. When admitted she presented the picture of extreme anemia; radial pulse hardly to be felt, rapid; the abdomen distended, very sensitive to the touch. Bimanual examination revealed an enlarged soft uterus behind the symphysis. To the left of it a mass of irregular shape, but apparently as large as a fetal head, slightly movable, giving a boggy impression in some places, decided fluctuation in others. Fluid in the peritoneal cavity was easily detected. In spite of the miserable general condition of the patient I decided to operate at once. Under narcosis fetal parts could be felt through the abdominal wall. On opening the abdominal cavity about two quarts of dark fluid blood escaped; the left tube, the seat of the placenta, was wide open, showing still bleeding vessels in its torn walls. The whole mass was covered by adherent gut and omentum; the fetus was surrounded by intact membranes and made slight movements even after its removal.

On reviewing all the symptoms and signs of tubal pregnancy in its various stages it will readily be seen that the difficulty of recognizing the condition changes with each case; that in some of the unruptured cases we are able to make a positive diagnosis with the help of an exact history, and the physical signs elicted by a thorough examination, and that in other cases we are unable to make a positive diagnosis because of the absence of typical symptoms and must be content to describe the condition rather indefinitely as one of "supposed" or "probable" ectopic gestation. When we consider the peril impending over this class of patients, when we think of the grave danger which threatens them in case of the development of some complication, the mere fact that we suspect (on some substantial basis of course), the existence of a tubal pregnancy is sufficient for practical purposes, for it puts us in a position to serve best the interest of our patients, than which there is of course no higher duty in our profession. I do not deny that we may frequently find that we have erred, but by these errors we will never harm our patient. But if we only once make a correct diagnosis we have the supreme satisfaction of knowing that we have saved a possibly doomed life, certainly one menaced by grave peril. I can give no better illustration of the dangerous position of a patient afflicted with tubal pregnancy, left to its natural course, than to refer to the statistics of cases collected by Schauta up to the year 1890, according to which out of 161 patients in the first half of pregnancy not interfered with, 132 died and only 29 recovered.

Little wonder indeed that there is a daily increase in the number of followers of that author who advises us to consider an ectopic gestation in the same light as a malignant growth and to remove it at the earliest possible moment. I personally have always adhered to this rule and have never tried to substitute for a surgical procedure any of the so-called simpler and less dangerous therapeutic measures, such as the galvanic current or the injection of morphin or other chemicals into the gestation-sac. While I do not for a moment doubt the possibility of these agents doing the required work of killing the fetus, I have good reason to believe that with the death of the fetus all danger from hemorrhage has not passed. I also believe that under these conditions the chances of the occurrence of secondary infection are greater. Once the diagnosis of an unruptured tubal pregnancy is established or even reasonably suspected, it is, I believe, in the best interest of the patient that the gestation-sac be removed as soon as circumstances will permit. Should there be a mistake in our diagnosis it has no further significance than that the patient was operated on perhaps somewhat sooner than she might have been with a correct diagnosis; for it is only existing pathologic conditions, which require removal sooner or later, that can be responsible for our error.

For the removal of a pregnant tube I have heretofore employed the abdominal incision, but in the light of wider experience with vaginal work, I think there are cases in which the tumor lies low in the pelvis, which can more easily be removed by an incision through the posterior fornix, in the same manner as we operate for the removal of small, freely movable ovarian cysts. The vaginal route, if practicable, is not only less dangerous for operation, but it also obviates stitch-hole abscesses so often encountered when the time for proper preparation, particularly of the skin, has not been allowed.

Our position is by no means so well defined and clear when we have to deal with a tubal abortion or a ruptured tube at the time of or soon after its occurrence. Still, considering the fact that in the early months of pregnancy this event is seldom, if ever,

followed by a single fatal hemorrhage, but that repeated attacks of shock and loss of blood are the rule, it seems only logical in these cases to resort at once to surgical procedures, to control further hemorrhage by opening the abdominal cavity and ligating the affected organ. It is but a natural feeling that in some desperate cases we should shrink from hastening the end by our interference; but as surgeons we must be free from such sentimentality. There are too many cases reported, where operations performed on moribund women have restored life, to allow us to watch the approaching end without having tried to avert it. Even should some patients succumb on the operating-table, we at least have the satisfaction of not having contributed to that end by a sin of omission.

Vigorous and continuous stimulation by all the means at our command is of course self-understood. Infusion of normal salt solution into the circulation has been so beneficial in its results that it ought always to be among the first therapeutic measures resorted to in these cases of extreme loss of blood. The apparatus for its application ought to be at hand; in desperate instances a vein may even be dissected out before operation, so as to enable us to infuse without loss of time, should that measure be indicated. I have always treated retro-uterine hematocele, after all the signs of active bleeding have disappeared, with wide incisions through the cul-de-sac and drainage, and have every reason to be satisfied with the result of this simple procedure.

Having reviewed thus somewhat in detail the diagnosis and treatment of this most serious and grave phenomenon, allow me to call your attention once more to the extreme importance of a correct diagnosis in this class of cases, and to urge that when an absolute diagnosis is impossible or difficult, that there is no condition in which the use of the knife is more justifiable. So many lives have been uselessly sacrificed in the past by the lack of recognition of this ailment, that we should try to make it a point of professional pride that, when the patient is seen before every hope has vanished she shall no longer be left to die because of our timidity.

There is one point left for me to insist upon, and I do so only because I have frequently seen the evil results accruing from it. I refer to the indiscriminate use of the curette upon women who are suffering from metrorrhagia, the curettement being accomplished often without a vaginal examination, or at least without a thorough one. I have dwelt sufficiently upon the symptomatology of tubal gestation to make it clear, I hope, that a metrorrhagia of some character is a constant accompaniment of the condition. It is always well, therefore, to bear this possibility in mind when called to see a woman from whose symptoms a probable diagnosis of "abortion" would be made. A careful, painstaking examination, even in the absence of a clear history, will frequently enable us to avoid the error of mistaking a tubal for an ended or partially ended uterine pregnancy. It should no longer happen that a woman suffering from an extra-uterine pregnancy should have her uterus curetted, packed with gauze, and be compelled to take hydrastis or ergot in heroic doses; for sooner or later, the true condition of affairs is bound to manifest itself, and then, when it is perhaps too late, the physician will find himself face to face with the gravest of emergencies. I said "It should no longer happen," and I am confident that as further study is given to the consideration of irregular uterine hemorrages by the general practitioner, the routine treatment of uterine and tubal diseases, and particularly of the pathologic conditions under consideration, will be relegated to the oblivion deserved, and that each case will receive that therapeutic application which our increasing skill in diagnosis and technic demands. Let me urge upon those of you who are in general practice, then, you who are the first to see and to examine these patients, to use your skill to the utmost, to abolish the routine treatment of hemorrhages from the uterine cavity and to restrict the use of drugs which cause uterine contractions to their proper spheres. Then I am certain that reports of cases of ectopic gestation will grow more plentiful in the same proportion as "deaths from internal hemorrhage" become more rare.

A FATAL CASE OF AFEBRILE ACUTE ENDOCARDITIS.

BY CHARLES O'DONOVAN, M.D.,
OF BALTIMORE, MD.

ON October 20, 1895, I was asked to see B. D., white, nineteen years of age, an unmarried man, engaged in teaching in a large school for boys. I found him to be rather thin and pale, but fairly well nourished considering his indoor work and the fact that he took very little exercise. His family history was good, except that his mother suffered frequently from severe attacks of rheumatism. He had himself always been healthy, though never robust. He was in bed and complained of severe pains in the abdomen, especially on the left side, just over the descending colon. His heart and lungs were sound at that time. His pulse was 84, and temperature 98.4° F. I examined his abdomen carefully, but failed to detect anything wrong. I ordered castor oil, to be followed in the morning by a moderate dose of Epsom salts. The next day he was much better, his bowels had moved freely, and his pain was gone. He complained, however, of feeling quite weak. I advised him to get up and to re-

turn the day after to his class, meanwhile taking care that his bowels should be regular, and ordered a light but nutritious and easily digested diet of eggs, milk, toast, broth, and light meats. I saw him next on October 28th, one week afterward, when he came into my office, complaining no longer of pain in the bowels, nor of any pain, but only of an intense weakness and a sense of constriction over the region of the heart. The change in his complexion was very marked; he had grown pale and ashy. His pulse was 96, but jerky. Auscultation revealed a murmur indicating aortic regurgitation, not as well defined as in an old case, but seeming to be caused by a very trifling insufficiency of valve action. All the other valves acted properly. He was ordered to bed as soon as he got home, and was given 20 grains of bromid of soda every four hours.

October 29th, 11 A.M. Pulse, 90; temperature, 98° F. The sense of constriction is gone; his appetite is good, and his bowels regular; he slept well; he has had no fever nor chill, yet the aortic regurgitant murmur is much more distinct, and a slight murmur begins to be apparent synchronous with the systole. Rest alone is ordered. October 30th, 11 A.M. Pulse, 90; temperature, 98⅕° F. His pulse is quite weak and compressible, and his temperature is reported to have been 97° F. at nine o'clock last night. The patient has been very comfortable; eats and sleeps well, and cannot realize that he is ill at all. Inside the heart, however, decided changes are taking place. The systolic murmur has become quite loud and rough, and the aortic murmur changes in character daily; the action of the heart, as a whole, is decidedly weaker.

October 31st, 11 A.M. Pulse, 90; temperature, 98° F. Feels very well. Slight endocardial changes since yesterday, but today could be made out for the first time a friction sound in the pericardium near the apex of the heart. Two coats of tincture of iodin were painted over the heart. Urinary analysis to-day showed neither albumin nor sugar. November 1st, 11 A.M. Pulse, 84; temperature, 98⅖° F; 9 P.M., 99⅖° F. About as yesterday; feels very well; pericarditis a trifle more pronounced; endocarditis but little changed; pulse weak still, showing some myocarditis; no chills; eats and sleeps well; no sweating. The iodin was continued. November 2nd, 11 A.M. Pulse, 84; temperature, 99° F.; 9 P.M., temperature, 99⅕° F. The aortic murmur seems less loud and much overshadowed by the systolic murmur, which is becoming louder and rougher daily. Pericardial friction sound is diminishing in intensity. Feels very well until he tries to get out of bed for anything, when his weakness becomes very apparent. Ordered to-day 40 drops of syrup of the iodid of iron three times a day, together with strict rest in bed. November 11th. The aortic diastolic sound is an undoubted valvular lesion. The systolic murmur seems to pervade both ventricles, and not to be limited to the location of the valves alone; there is also a presystolic *bruit*, all of which seems to indicate a general roughness of the ventricular endocardium. The sound of valve closure is sharp and fairly well defined, so that at the present there seems to be little or no mitral regurgitation. The systolic sound is, however, quite loud and unmistakable. There is no pericardial friction sound. His general condition is excellent; he is still in bed. The pulse is 84, stronger in tone, and fuller in volume. Urine, acid; specific gravity, 1027; no albumin; no sugar. The iodin was discontinued at the disappearance of the pericarditis.

The first thing that strikes one in studying this case is the remarkably slight elevation of temperature that was observed. The patient was a very intelligent young man, and had been carefully watched by a friend who lived in the same house with him, and who had access to him at all hours. They were both instructed to be on the lookout for any chill or apparent rise of temperature, and to use the thermometer at once, leaving it for my inspection at the next visit. I have every reason to believe in their ability to carry out my instructions, yet the highest temperature that I found was 99⅖° F., and, on the contrary, it several times fell below the normal, going to 97⅗° F. at one time. This makes one suspect that the murmurs might be of hemic origin rather than due to an endocarditis. I was myself inclined at first to consider them so, but no one could listen to the harsh, blowing, and churning sounds produced just beneath the ear without feeling sure that they arose from a roughened endocardium, and not from any altered condition of the blood. The changes, too, from day to day, increasing in intensity with the development of the disease, and now slowly subsiding, but with two distinct murmurs, readily located in the ventricles and at the aortic valve, make the diagnosis even more certain. Additional testimony is added by the intercurrent pericarditis.

In the most severe form of endocarditis the heart has been proven to be invaded by streptococci, staphylococci, and pneumococci, but other organisms have been found also. It may be that lighter cases may arise from invasion by less malignant organisms, many of which escape detection altogether, or are ascribed to intercurrent rheumatism or other diseases. This patient presented no sign of rheumatism, nor of any of the other diseases in the course of which endocarditis is usually anticipated. Certainly in this case the temperature presented no satisfactory ratio in comparison with the existing heart trouble. While the man was up and at his work he was very weak, and grew daily weaker at a rapid rate. After he was put to bed and kept under careful observation the intracardial changes from day to day were very marked, and each indicated the rapid proliferation of new tissue

and considerable roughening of the surface of the endocardium. Yet, with it all, no fever appeared; and, moreover, as soon as the extra strain, induced by the erect posture or by exercise, was removed from his heart, he experienced at once almost entire relief. The sense of extreme weakness which led him to seek advice, and the dyspnea that was not oppressive but was becoming so, and the very disagreeable sense of constriction about the thorax, all were relieved within twenty-four hours after he went to bed. And from this we may see clearly the most important indication in the matter of treatment. He was given a little bromid because he was quite nervous about his condition, but he took it only for about twenty four hours. After that he had no medicine; nothing but rest. When the pericarditis made its appearance enough tincture of iodin was painted twice a day over the entire region of the heart to burn the skin a little, but as soon as the pericarditis yielded this treatment was stopped. The case progressed so satisfactorily that no further treatment was indicated so far as the heart alone was concerned, but because of the consequent anemia it was thought advisable to give iron in some form, and for that reason the syrup of the iodid was given in 40-drop doses. Already I think I can perceive that the heart is beginning to accommodate itself to the new condition of affairs. I think that he will recover with a damaged aortic valve, but I hope that his mitral and tricuspid valves will entirely escape. At present there seems to be very little disturbance with their function.

The first part of this paper was written while his case was under treatment for the purpose of calling attention to the fact that serious endocarditis can exist with but slight elevation of temperature, and this, I thought at the time, was the only interesting feature about the case. The man at that time was tractable and obedient, and gave every promise of a satisfactory result. Under advice he continued in bed, and improved slowly but surely, so that by December 25th he was allowed to be up and about the room for a short while each day. He was still excessively weak and anemic, tiring very quickly when out of bed, but feeling perfectly well as soon as he lay down again. His appetite continued to be very good, but he assimilated badly and gained strength very slowly. His temperature was $98\frac{2}{5}^{\circ}$ F. in the morning and evening. He still took the syrup of the iodid of iron in 10-drop doses after each meal. The valves of both the aorta and pulmonary artery showed disorder, giving rise to distinct regurgitant murmurs at each valve. The other valves were all right, and the peculiar vibratory churning sounds in the heart had by this time entirely ceased. He was allowed to walk about the house, being cautioned not to overtax his strength. He behaved very well until January 3, 1896, when, for his first venture out of the house, he went into the country some thirty miles by rail, to the funeral of a friend. The weather, at that time, was intensely cold. The next day I was told that he had returned to his work as school-teacher, saying that he felt perfectly well, that he had stood the fatigue of the day before without harm, and that he felt that he might as well be free from any restraint. I predicted then his sure relapse, and warned his friends of the suicidal folly of his action. I must acknowledge that at the time I had little credit for my prediction. I did not see the patient again until March 2, 1896, two months after his emancipation. Then he came to my office, complaining of feeling very weak and tired after his classes. He looked very thin and white. While sitting in a chair his pulse was 126, and it quickened very much when he stood up or walked. He was not aware of any chills or fever. His pulse impact was very fair, but the arterial tension was very low and the artery easily compressible. He had some twinges of rheumatism in his right leg. His appetite was gone. He had a constant short, hacking cough, with little expectoration, which became more frequent and annoying when he lay down, especially at night. Examination of his lungs revealed nothing abnormal, but in his heart the change was marked. The whole organ seemed filled with a seething, churning, fluid, in which the valvular sounds could not be made out. It was as if all valvular action was lost. I gave the gravest prognosis, and advised him to give up everything and go to bed at once for a prolonged course of rest and treatment. He preferred to go to a hospital, and accordingly went that day to St. Joseph's Hospital, where he continued to grow worse until he died, about a week later.

One point arises that is of interest. How long should an actively diseased heart be spared? Can any rule be laid down for the length of time that such a person should be kept in bed? As much as anything else, this case is interesting for the complete answer that it gives to these questions, showing the utter futility of making any certain rules for such matters. In no case can one foretell the length of time to be passed in bed; each case must be studied on its own merits. Patients with the lightest cases do not invariably recover, the heart muscle being frequently weakened out of all proportion to the gravity of the manifest symptoms, as in the case here recorded. The temperature-chart does not give the best index to the gravity of the case. The study of the pulse in its force, its regularity, and its rapidity is a wiser course. Watch the effect on

the pulse of effort, the difference between standing, walking, or lying down. Until the heart is able to bear up against the varying strain of these different conditions the affair may still be considered serious. If in doubt it is better to be over cautious.

WAR ARTICLES.

NEWS OF THE WEEK.

THE transport "Olivette," with 262 wounded and convalescent soldiers from the trenches before Santiago on board, arrived in New York harbor on July 16th. One hundred of the wounded were at once transferred to the Marine Hospital at Stapleton, Staten Island, 50 to St. Peter's Hospital, Brooklyn, and 54 to the Long Island College Hospital, Brooklyn, the 58 convalescents being taken to Governor's Island. While all the men seemed in excellent spirits and rapidly gaining in health and strength, the appearance of all as far as clothing was concerned was most deplorable. Most of them were literally in rags, and not a few were without covering for their feet. Among the whole 262 there was not one complete uniform, owing to the fact that as fast as the wounded were taken from the firing lines to the field hospitals their clothing was cut off so as to get at their wounds, and when they were in condition to be moved they were hastily clad in whatever scraps of raiment came first to hand. This, in most cases, was clothing taken from the dead on the field or from those who died of wounds in the hospitals. Unfortunately, no provision was made for clothing the men when they were placed on the transport. It is expected that an abundant supply of clothing will be furnished to them at once, the Woman's War Relief Association and other similar organizations having volunteered to supply all that is necessary. Very few of the men had any complaints to make of their treatment, and all apparently regarded the hardships they had undergone as a matter of course. The uppermost thought in the minds of many, not too badly wounded for future service, was the question of when they would be well enough to get to the front again. It is probable that the next boat load of wounded soldiers brought from the front will be taken to Bellevue Hospital, where 450 vacant cots have been placed in the Sturgis Pavilion for the use of the United States Government.

. . . . . .

Alleged lack of sufficient food furnished by the Government to the Volunteer troops awaiting transportation to the front has resulted in mutiny during the past week among the members of the Third Wisconsin Regiment at Charleston, S. C., and the recruits for the Seventy-first New York at Camp Black. Three men of the Seventy-first fainted when on guard duty as a result of lack of nourishment. Since going into camp but two meals a day have been furnished, and these have consisted of coffee and bread only, the supply of the latter in a number of instances proving entirely inadequate to the demand. This condition of affairs undoubtedly is the fault of the Commissary Department at Washington, and it is to be sincerely regretted that the steps necessary to obtain proper food for those who are to risk health and life for their country are so hedged about by red tape as to render the hope of immediate relief uncertain.

. . . . . .

The attitude assumed by the Cuban soldiers at Siboney and El Caney in absolutely refusing to perform their share of the labor necessary for digging intrenchments, making roads, transporting artillery and supplies, etc., such work being to their minds unsuited to free men, may afford an indication of the condition which will face our Government when the management of Cuba falls to its hands. It will be remembered that the Southern negroes, when newly freed from slavery, had very much the same idea of freedom. It meant to them freedom from work, freedom to pass their days in one long season of "*dolce far niente*," and especially freedom to draw upon the United States Commissary Department for food, clothing, and every necessary.

. . . . . .

It took a generation or more to educate the Southern negro into the meaning of the word freedom and it will take as long to teach the Cubans that without labor their incomes will be slim and their bill of fare much abbreviated. The situation and outlook are not depressing, however. Capital is already waiting in abundance for investment in the fertile tobacco and fruit lands of Cuba; men from "the States" will be sent by thousands to perform the necessary labor, and example will soon lead the natives to follow the course of the Northern wage-earners.

. . . . . .

Was there method in the continued requests for delays and truces requested by General Toral ostensibly to allow him to consult his home government regarding the surrender of Santiago? Spain's strongest ally is disease, and she knows it well. Each day of delay brought yellow fever nearer as a reinforcement. Every ragged, unclean, starving outcast from the city who came to beg rations of our men helped to spread the seed of contagion. It would be illegitimate warfare to poison the water-supply of

Santiago; what then is the ethical status of the spreading of a malignant contagion throughout an army of men in peculiarly fit condition for its most effective work?

. . . . . .

More alarming than any story of battle on land or sea is the report of cases of yellow fever among our soldiers at Santiago. Conditions are ripe for its deadly harvest. The men have been working almost to exhaustion in intrenchments of newly turned-up earth under a scorching sun, alternating with tropical downpours which drenched them to the skin. True, careful rules have been promulgated for their direction in matters of hygiene and diet, but as we have before suggested, it is one thing to formulate rules for personal habits and quite another matter to enforce them. Fortunately, the facilities for caring for the fever patients, while perhaps not ample, are still wonderfully complete considering the time available for preparation, and in Drs. Sternberg and Guiteras there is embodied the practical knowledge of the world in the handling of this dreaded pest, not only as to curative treatment, but covering measures to prevent its spread.

. . . . . .

Dr. Alvah H. Doty's suggestion that yellow fever patients be brought by transports directly to New York City or other Northern hospitals sounds like practical common sense. As he points out, New York is north of the fever belt, its hospitals are efficient and experienced in handling great numbers of sufferers from contagious diseases, and its quarantine regulations are ample to guard against any spreading of disease. Conversely it would certainly be a grave mistake to take yellow-fever patients or suspects to any port or hospital in the Southern States, where climatic conditions render necessary only the sowing of the seed to start an epidemic of unknowable extent and severity.

. . . . . .

Now that Santiago has fallen the Government evinces great wisdom in withdrawing our soldiers, with the exception of a few regiments of immune and acclimated troops to "hold our winnings," until fall, if necessary, before continuing active campaigning against Havana and the remainder of Cuba, and the men will heartily welcome a removal to the comparatively cool climate of the States. As we go to press, the negotiations for peace are becoming the subject of newspaper talk to an extent which would indicate that the end is near and that the remaining conflicts will be waged by diplomats instead of by army and navy, a consummation devoutly to be wished.

WINDS AND WEATHER IN MANILA.

BY JOSEPH EARLE STEVENS,
OF BOSTON.

Now that our soldier boys are going to Manila and our merchants beginning to feel that Admiral Dewey has won for us a new El Dorado, a natural curiosity is aroused as to what are some of the ordinary conditions of existence prevailing in the far off Philippines. What is the weather like out there? How do the people dress? What is there to eat? Is it healthy? and a score of similar questions are daily asked of me as a result of the fact that I kept house in Manila for the best part of two years and took numerous excursions into many parts of the Archipelago.

More or less statistical and descriptive matter has been written on the Philippines since the guns of our fleet silenced the batteries at Cavité and sunk the Spanish ships that in my day used to swing peacefully at anchor off the breakwater, but for the reason that few correspondents have lived long in the capital some of the simple things of everyday life have escaped their attention.

As ought now to be known the climate in Manila is hot, though not unhealthy, and persons of ordinary constitution who are not especially subject to fevers or stomach troubles, can live there with equanimity. I take Manila as a standpoint, for just as France is Paris, so are the Philippines Manila, and everything feels the influence exerted by the capital. From noon until three o'clock each day the mercury visits the cross-bars on the thermometer lying between 90° and 95° F., except at such times as the heavy clouds of the rainy season shut off the sun's attentions and keep it 5° or 10° below. Fortunately, the nights are rarely uncomfortable, and 85° F. is very high for the temperature of one's bedroom. In the winter months, that run, as with us, from November to March, I have often shivered on the way to an early morning tub, as the Englishmen call it, with the mercury at 70° F., and in the hours before sunrise temperatures of 60° have even been recorded. The late afternoons of the winter months are as cool and delightful as one could wish, and it is only the hot, dry days of March, April, and May —when the fresh breezes of the southwest monsoon have not been fairly incubated—that the continued heat becomes annoying. The spell is broken, however, by the heavy thunderstorms which roll along in the afternoons of June and July, and with the coming of the strong southwest wind the rainy season begins. Not that it rains continuously, but that every now and then there will be seven or eight stormy days, to be followed, perhaps, by as many dull but fair ones. Those are the times when one's

boots grow moldy and one's tweed suits have to be hung out on the clothes-line at the first suspicion of sunshine.

As a climax to the wet season come the typhoons, which are more popular in the months of August and September than any other, and these fierce circular storms seem to blow or wash every atom of disease and dirt out of Manila. These storms, which are a terror to mariners on the China coast as well as to the inhabitants of Japan and the Philippines, come to life away down in the Pacific to the southeast of the Archipelago, gyrate about till they gain strength enough to swirl up along the Cordilleras on the back coast of Luzon, cut through a gap in the mountains some 100 miles north of Manila, and then sizzle over to Formosa and the China coast on their destructive voyages to Japan.

The typhoons, anywhere from 50 to 200 miles in diameter, move forward at a slow rate of perhaps only 10 or 12 miles an hour, but the winds inside the circle often acquire a rotary speed of more than 120 miles an hour. Manila, owing to her position behind the mountains of the east coast, below the gap through which these disturbances are wont to cross into the China Sea, rarely gets more than a good taste of the blow, but now and then a typhoon which has lost its way will sail squarely across the town and carry off the roofs of a thousand or two houses in its efforts to find out where it is bound.

The excellent meteorological observatory in Manila, which hitherto was conducted by the Jesuit priests, has had the reputation of being the most complete institution of its kind east of Naples and west of Washington, usually gives warning of the approach of these typhoons a day or so before their actual arrival, and the town is therefore ready to receive them. But once in a while, as in the case of the great storm back in the eighties, the elements give an exhibition without previous notice. The last typhoon, which almost razed Manila to the ground, came from a clear sky, and was so narrow in diameter and moved so fast that in four hours it had come and gone. It struck the city at about 10 A.M., and the deadly gale unroofed houses, blew buildings bodily over, picked up carriages and carried them up the streets, and prostrated trees and wires in all directions. Shortly before noon the wind and rain ceased, the sun came out pleasantly, and every one thought danger was over. But it was merely the calm spot, in the center of the cyclone's vortex, passing over the city, and by 12.30 P.M. tremendous squalls were coming from an exactly opposite quarter to those of an hour before. The roofs which were not carried off by the earlier winds were ripped up like so much paper under the force applied in the new direction, native houses, sheltered, perhaps, from the northeast, were carried off by the terrific gale from the southwest, big logs from lumberyards were caught up and hurled across the River Pasig, and every ship in the bay—big or little—broke adrift, to be washed high and dry on the beach.

Happily, Manila is not often visited by such disturbances as the one above recorded, but nevertheless it is not beyond the bounds of probability that the foreign resident may some day suffer a similar experience to that encountered by my friend the Englishman, who, after a heavy blow, returned from his office to find only his upright piano standing on the spot where he had left his light-built house in the morning, the rest of his things having journeyed on to the next village.

With the blows and rains of the months from July to October come the floods, and as Manila proper is scarcely more than a foot or two above high water, the land is often covered with the overflow of the Pasig, which is unable to handle all the water that is dumped into it by the big lake—Laguna de Bay—sleeping up country at the foot of the hills. This latter, shaped something like an exaggerated "W," forty miles from point to point, is a vast slop-basin, into which run all the washings from the mountain slopes that surround it. It lies almost four feet above the level of Manila itself, and its only outlet is the River Pasig, which, nine or ten miles in length, wobbles down through the very heart of Manila to the bay, and carries off the surplus water discarded by the lake. For years and years the inhabitants of the capital have long thought that a sudden earthquake would send this vast mass of water tumbling down over the low land, which exists only on that side of the lake nearest to Manila, and every successive flood only seems to make them feel that their city is literally between the devil and the deep sea.

Curious as it may seem, the city is never healthier than during these periods when boats take the place of carriages and dry ground is at a premium. For Manila is practically without a drainage system, and what is not looked after by the pigs or dried up by the hot sun must be gotten rid of by other means.

To conclude, then, the climate of Manila is not unbearable. In the winter months the breezes of the northeast monsoon, which blows for the best part of five months, keep the mercury from flying high, and bring clear days and cool nights. In the lull between the monsoons comes the hot weather of March, April, and May that is harder to bear, but with the advent of the southwest trades, the sea breeze takes heart, and with its friends, the clouds and

rain, makes one forget the temperature in his efforts to keep the mold out of his clothes or the roof on his house.

YELLOW FEVER; ITS DIAGNOSIS AND TREATMENT.

BY J. EDWARD STUBBERT, M.D.,
OF NEW YORK;
LECTURER ON TROPICAL DISEASES, UNIVERSITY BELLEVUE HOSPITAL MEDICAL COLLEGE; LATE CHIEF SURGEON OF THE NICARAGUA CANAL COMPANY.

THE despatches from Surgeon-General Sternberg, announcing the presence of yellow fever among our troops in front of Santiago, have caused widespread anxiety among American homes. While we have no reason to doubt the fact of the presence of the dread disease in our camps, there is considerable encouragement in the statement of Dr. Valiente that there is no especial danger from yellow fever along the southern coast, and that the prevailing fever in that section during the rainy season is of malarial origin. The reserve of Dr. Sternberg is well advised, and he undoubtedly recognizes the danger of the panic that is universally present in districts infected with yellow fever. In West-Indian districts yellow fever and malarial fevers are generally concomitant, and it is often very difficult for experts to determine between the former and pernicious malaria. Greater uncertainty and confusion will necessarily occur among our surgeons, most of whom have never had the opportunity of becoming familiar with the two diseases; therefore, considerable allowance must be made for the reports we see daily in the press of "additional cases," and a large percentage assumed to be of coast fever.

The yellow-fever germ depends for existence upon humidity, heat, and a certain amount of filth and unsanitary conditions. The bacillus icteroides does not live as a rule on high ground on sites exposed to sunshine and breezes. The means of infection in the present epidemic is probably to be located in the large number of refugees who were allowed to enter our camps; this was a mistake that cannot be remedied, but should have been foreseen, and will be a warning to the Medical Department of the Army in Porto Rico, and at other points in Cuba.

The questions before our surgeons at the present moment are: (1) prophylaxis; (2) diagnosis; (3) treatment. Prophylaxis should consist in an iron-bound quarantine absolutely controlled by the Medical Department. Red tape and bureaucracy may be feasible in delaying military movements, for the enemy may also be slow; not so with yellow fever; the Medical Department must be free to act promptly as necessity indicates. As far as possible negroes and immune troops should be used in and around Santiago; those not so classified should be placed in camps on elevations overlooking the sea when possible; if not, then on high points inland. There should be conveniently located suspect and pest camps; there should be a medical inspection every day, when the surgeons should carefully overlook every soldier, select out even mildly suspicious cases, and send them to the suspect camp until it be determined whether the case be one of malarial or yellow fever. At all points where patients have been located clothing, tents, brush, and everything else capable of providing a lodgment for the germ should be destroyed by fire or thoroughly disinfected. If such rigorous methods are employed there is little danger of the establishment of more foci of disease among our camps.

During the work on the Nicaragua Canal not a single focus of this disease was established along the Company's line, although yellow fever was present each year on the same coast directly north and south of the Company's headquarters, and there were daily arrivals of steamers and small schooners at the ports. On the Pacific Coast of Nicaragua each year yellow fever appears in the cities located along the line of railroad from Corinto. The comparative immunity on the Atlantic side was due undoubtedly to rigorous quarantine and prophylaxis, in the application of which the Medical Department of the Canal Company recognized no superior in taking orders or seeking advice. For bureaucracy yellow fever has no respect.

Diagnosis.—The scientific method of diagnosis by the agglutination tests are of great value, as Tonatre has said, in labelling the disease, but in camp work the greatest reliance must be placed upon clinical diagnosis. The serum test is more accurate on the second day of the disease than later, but there are clinical features which, to an eye accustomed to the symptoms of yellow fever, will infallibly establish the diagnosis in a vast majority of cases during the first day. Neither can the surgeon invariably exclude yellow fever on account of the presence of the malarial plasmodium.

Symptoms.—Some cases are ushered in by the historical chill, but all are preceded by rigors of more or less severity. In most instances the facial expression is characteristic, congestion of the whole countenance and suffusion of the eyes, accompanied by pain in the back and limbs, and very severe bilateral-frontal and postorbital headache. The initial temperature is usually about 102° F. and the average maximum, less than 104° F., is reached generally within the first six hours of the disease. The remission occurs sometimes on the third day, rarely on the fifth, generally on the fourth, and lasts, on an

average, six hours. The average length of the third stage is three days. Black vomit appears in most cases as early as the third day, but nausea is present from the incipiency of the disease. Decrease of the amount of urine is observed on the second day in nearly every case, and albumin on the third or fourth day. It will be found in large quantities in about 98 per cent. of the cases under observation, and will rarely be absent. In a number of cases treated by the writer the application of the heat test alone was sufficient to coagulate the urine into a solid mass that would remain in an inverted test-tube. The amount of albumin seems to have no relative effect upon the rapidity with which the urine clears up during the stage of decline. In most cases the albumin will disappear suddenly with the fall of temperature during the third stage of the disease, but in exceptional instances traces are discernible for some time during convalescence. Jaundice is by no means a constant symptom, and rarely is it present before the fifth or sixth day.

Constipation is found in most cases all through the disease, sometimes diarrhea supervenes during the third stage, and at times, where intense general jaundice is present, the defecations are pasty and clay-colored. In a majority of patients the mind will remain clear until the end of the disease, whether that end be reached in death or recovery. The pulse is generally slow, and there is a wide divergence between it and the temperature. Some cases are marked by great depression, intermittency of the pulse, algid surface, and during the third stage a great difference between the sublingual and rectal temperatures; the former was, in one patient of the writer's, 99.2° while the rectal was 102.6° F. Generally on the night of the third day or morning of the fourth the temperature drops *suddenly* three to four degrees, ushering in the stage of remission or quietude; at its close the temperature again rises to nearly the height attained in the first stage, and then in favorable cases begins to decline by lysis; in fatal cases the stage of remission is very short and followed by a high remittent temperature. In abortive cases, especially when the epidemic is on the decline, convalescence follows immediately upon the stage of remission. During the third stage, or that of decline, the temperature and pulse gradually approximate.

The disease most likely to be confounded with yellow fever in our Santiago camps is pernicious malaria; the following comparison presents their most prominent points of differentiation.

Dengue or break-bone fever is a disease having its habitat in warm climates, and has been confounded with mild cases of yellow fever. The reason is not apparent, for their clinical histories are distinct. The following table shows a comparison of the more prominent symptoms common to both diseases:

YELLOW FEVER.	PERNICIOUS MALARIA.
Headache bilateral-frontal, and post-orbital.	Headache generally unilateral frontal, and temporal.
Temperature and pulse divergent; temperature rarely higher than 104° F.	Temperature and pulse correlative; temperature generally 105° to 107° F.
Albumin present in large quantities early in the disease.	Albumin rarely present.
Quinin has no effect on the progress of the disease.	Quinin has a specific effect if given hypodermically and early.
Stage of remission on third or fourth day.	Remission not present.
Attacks new arrivals.	Generally history of chronic malarial infection.
Always history of exposure to infection.	No history of exposure to infection.
Black vomit appears on third or fourth day.	Black vomit appears within thirty-six hours.
Hematuria very rarely present.	Hematuria a marked symptom.
Liver unchanged.	Liver enlarged and tender.

YELLOW FEVER.	DENGUE FEVER.
Cephalalgia and nephralgia are the characteristic pains, and are constant.	Pain most severe in joints and muscles, and is *paroxysmal*.
Pulse and temperature divergent.	Pulse and temperature correlative.
The slowing of the pulse begins early in the disease.	The slowing of the pulse occurs late in the disease.
Congestion of face early in the disease. No edema.	Rash on face, followed quickly by edema.
Albuminuria.	Albuminuria absent.
Icterus.	Icterus absent.
Black vomit.	Black vomit absent.
No eruption.	Polymorphous eruption, followed by desquamation.

Treatment.—The mortality of yellow fever has been decreased considerably in recent years. General Sternberg's treatment has given the remarkably low death-rate of 15.9 per cent. in Havana, 7.3 per cent. in the United States, Brazil, and Cuba, and 4.7 per cent. in Florida. The average death-rates range between twenty and fifty per cent.

While awaiting the full development of the antitoxin of Sanarelli, our treatment of this disease must be expectant and symptomatic, together with careful nursing. All authorities agree upon the first two steps to be taken: Purge the patient with a single dose of one-half to a full tumblerful of castor oil; then produce profuse diaphoresis either by hot air or mustard pediluvia. After the first cathartic has acted freely, a gentle daily movement of the bowels should be maintained by the following:

℞ Magnesiæ sulph.
Magnesiæ carb. } aa . . 15.00
Sulphur precipitatis
Sacch. lactis } aa . . . 8.00.
Pulv. anisi
M. Sig. Teaspoonful once or twice a day.

This is very necessary to prevent constipation and secondary intoxication.

Diet.—Diet throughout the disease should be restricted to milk and Vichy in equal parts. During the first two or three days the Vichy may be taken alone if more pleasing to the patient. It stimulates hepatic circulation and renal secretion, and some be-

lieve that it dilutes or neutralizes the icteroid toxin. During the second and third stages the patient should be urged to take milk.

Antipyretics.—There will be great temptation to administer antipyrin or some similar drug during the first stage, but unless the temperature rises above 104° F., it would be unadvisable, because yellow fever is a cyclic disease that cannot thus be turned from its course, and because of the danger of cardiac depression in the second stage. Baths are of doubtful benefit, excepting for the comfort of the patient. The urine should be measured and examined twice a day, and at the first signs of suppression 1/100 of a grain of nitroglycerin given for two to three doses at intervals of six hours, and followed by digitalis and saline diuretics. Poultices are of occasional benefit. A cardinal point of treatment is to produce copious diuresis. If this be accomplished the patient will generally recover. The larger quantity of urine passed the smaller will be the percentage of albumin, and, therefore, in direct ratio, the less danger of death. Buanger-Ferand has recommended large enemata of cold water to reduce the temperature. Undoubtedly this would be one result of such injections, but a more important one, to my mind, would be the diuresis thus established. These enemata should be given twice a day in as large quantities as can be retained and absorbed by the rectum.

Nausea and Vomiting.—Most authorities are opposed to the use of emetics in this disease. However, the writer has seen the most gratifying results follow a single emetic dose of ipecac if given as soon as a *tendency to vomit* is shown in the first stage. If this be followed by copious draughts of tepid water until the stomach is well cleaned, and then $\frac{1}{8}$ of a grain of morphin given hypodermatically to quiet the stomach, the patient will feel much relieved, and thereafter will experience very much less nausea. This special treatment should never be entrusted to a nurse. Ipecac or morphin given at the wrong time are capable of great harm to the patient, but there is a moment, generally once only in the first stage, when their intelligent use seems to be indicated. It appears to abate severe gastric disturbances. Other symptomatic treatment for nausea consists of the use of $\frac{1}{4}$ of a grain of carbolic acid in one dram of peppermint-water every two or three hours, cracked ice, and sinapisms.

Morphin.—Much opposition is recorded against the use of opiates in yellow fever. In the abstract the objections are well founded, especially where there is much danger of anuria. There can be no infallible rule laid down, I believe, but the physician should be governed by symptoms, always bearing in mind the danger of suppression of urine. Given a case in which diuresis is well established, or even in which it is fairly copious, I believe the very occasional administration of $\frac{1}{12}$ to $\frac{1}{8}$ of a grain of morphin hypodermatically is not only justified, but indicated, to quiet the jactitations of the patients, and to relieve the nausea that does not yield to the other remedies suggested. If carefully watched there can be no danger to the patient, and the relief obtained does much toward conserving strength for the stage of depression. During the epidemic in Salvador in 1894 the German and native physicians steadfastly refused to administer morphin because theoretically wrong. The writer used it from two to six times in nearly every case. The results, eleven-per-cent. fatality, as against over forty-per-cent. fatality among the patients of the German and native physicians, would seem to indicate that practice is at times better for the patient than theory.

Stimulants.—Champagne is very universally used, as well as brandy. They should be given in small quantities, often repeated, and ice cold. Kola is strongly advocated by the French school, but I have seldom seen good results from its use, and it certainly is distasteful to the patient.

A summary of treatment may be, primarily, free catharsis and diaphoresis. Secondarily, constant avoidance of anuria and constipation, mild gastric and intestinal antisepsis, careful watching for and combating advance symptoms, and good nursing. Add to this Tonotri's excellent advice, "Battle to the last," and many patients who are apparently hopelessly ill may be saved.

THE ARMY HOSPITAL AT SIBONEY.[1]

By RAYMOND SPEAR, M.D.,
ASSISTANT-SURGEON, UNITED STATES NAVY, ON BOARD FLAGSHIP "NEW YORK."

THE army general hospital for the wounded and sick soldiers attached to the army before Santiago is situated at Siboney, about eight miles distant from Santiago. When a man is wounded at the front he retires to the rear and receives a first-aid dressing, and is sent to a divisional hospital; from here he is conveyed to the general hospital at Siboney by an ambulance. The roads are very rough and it requires a certain amount of strength to stand the journey, therefore, those who have been very badly wounded are retained at the divisional hospital until they are able to bear transportation.

The hospital is composed of wards made by plac-

[1] Surgeon Spear's paper here printed was mailed from the flagship "New York" on July 7th, but was delayed in transmission. It will be remembered that shortly after that date, by order of General Miles, Siboney was completely destroyed by fire on account of its unsanitary condition, and in order to lessen the danger of infection among the refugees and troops.—ED.

ing tents end to end; the operating-room is constructed in the same manner, and contains six operating-tables and baths for instruments, etc. The wounded are all taken into the operating-room as soon as possible. Here their wounds are dressed, necessary operations performed, a tag, upon which is written the patient's name and company, the injury, what was done, and when the wound requires a new dressing, is pinned to the clothing of each, and they are then sent to the ward and placed on a cot.

During the time this little operating-room has been in service more operations have been performed in it than in any other place of its size in the history of the world. Wounds of every organ in the body have been treated on the six tables around which worked Army and Navy, civilian, Red Cross, and Cuban doctors, assisted by Red-Cross nurses and Army hospital stewards and attendants. It was a novel sight to see difficult brain operations being performed by candle light in more than one instance.

The wounds treated were produced principally by Mauser bullets; others were inflicted by No. .43-caliber brass-jacketed balls, and still others were by flying pieces of shells. The wounds were very easy to distinguish; the small Mauser bullet many times made nothing but a small perforating wound, the tissues not being lacerated in the least. When they struck a bone the latter was either perforated, grooved, or splintered, but never badly, only a few amputations being required for this reason. The brass-jacketed bullet, on the other hand, lacerated everything it struck, soft and hard tissues alike. The injuries from the fragments of shell varied according to the size of the piece of projectile, from slight to severe wounds. The wound of exit of almost all of the bullets was larger than that of entrance. Many times, however, the exit-wound produced by a Mauser bullet was about the same size as the entrance-wound, and it was with difficulty that they could be distinguished.

A curious fact was the number of Mauser bullets that were found lodged in the tissues. Probably twenty per cent. did not penetrate deeply. This was contrary to expectation, the range and velocity of this ball being so great. It may be explained by the fact that the Spanish ammunition may have been old, or the leaves and grass through which many of the bullets passed impeded their course, or the elasticity of the living tissues may have had some effect on it.

Most of the killed received their wound in the head and abdomen. It is surprising what the human body can stand. In the hospital tents one can speak with men who have bullet wounds through their brains and hearts; soldiers possessing punctured lungs and livers walk about with little discomfort. There were quite a number of brain cases. These patients were all operated on, and so far have done remarkably well. Large pieces of bone and brain matter were frequently removed, with apparently little effect on the patient other than a beneficial one. There were a few cases of undoubted heart wounds, the subjects of which were getting along nicely.

Lung wounds were frequent, many patients proudly showing two separate punctures, and the only symptoms they presented were a little pain on breathing, and some coughing up of slight quantities of blood. Traumatic pneumonia has been very rare.

There were some penetrating wounds of the abdomen by the Mauser bullets that presented no symptoms whatever. These cases were rare, however, showing that most of those who received abdominal wounds had probably died, as they were not brought into the hospital.

The testicles and penis were not exempt from wounds, but the small bullet did not do very much damage in these localities. There has not been a case requiring castration or amputation of the penis up to date. The arteries did not escape the Mauser. There were quite a number of severed or injured arteries which resulted in traumatic aneurisms. These patients usually presented discoloration by effused blood in the surrounding parts, swelling, pain from pressure on the surrounding nerves, and a pulsating tumor.

The wounds of the bones were very interesting. The old bullet produced such shattering and splintering of the bones of the extremities that amputation was frequently indicated. The small, modern bullet makes amputation comparatively rare, resections and removal of splinters and drainage being all that is necessary.

There were many peculiar cases. One man was shot through the head, the ball entering his left ear and coming out just under his right eye, apparently not incapacitating him in the least. Another man was shot through the longitudinal sinus and cerebellum, and will live to tell all about it. On the other hand, there were men who were shot through both eyes, and will never see again. But these are the fortunes of war, and all must learn to bear them.

There was a small percentage of infected cases. This was due to the first-aid dressings which were applied. Some of the men being under fire could not have their wounds dressed for several hours, and these were the cases which seemed to constitute the large proportion of the infected class. If the wounds had been sealed with collodion immediately the proportion of infected cases would in all probability have been less.

AGUINALDO AND THE PHILIPPINE REPUBLIC —MEASLES IN THE TROPICS—A UNIQUE LOVE TOKEN—INCONVENIENCES OF AN INLAND CAMPAIGN.

[From Our Special Correspondent.]

WITH ADMIRAL DEWEY'S SQUADRON, OFF MANILA, PHILIPPINE ISLANDS, June 6, 1898.

THE situation here is becoming more complicated every day. The Americans are watching in vain for reinforcements, the Spaniards are scanning the horizon for signs of the four Spanish battle-ships which the Archbishop, in his last proclamation, declared were on their way, and the insurgents under Aguinaldo are talking of the new republic which is to be inaugurated under the protection of "the great American nation," as their leader calls the United States in his proclamation to the natives under date of May 24th.

Since my last letter I have spent some time on shore, and thanks to a smattering of Spanish, picked up in South America, have been able to make my way about Binondo and the outlying wards of Manila without molestation. Various subterfuges are resorted to by American newspaper correspondents to enable them to remain safely in Manila during the present panic. I know of one who passes himself off as a German from Berlin, and another who is supposed by the Spanish officers with whom he fraternizes to be employed by a French paper. Non-combatants are taking refuge at Cavité almost daily, and there are ten ships lying in the river waiting to carry away foreign residents when Dewey shall give notice that the bombardment of Manila is about to begin. What is to be done with the Spanish women and children is still a mystery, for they would not be safe in the interior, where the insurgents, flushed with the scent of victory in the air, can hardly be restrained.

The dignitaries of the Spanish Church, who doubtless fear that their occupation will be gone if the *ægis* of a great Protestant power like the United States is thrown around the ignorant and superstitious people on the fruits of whose labor they have fattened so long, are doing what they can to instil into the minds of their parishioners the belief that if Manila falls into the hands of the Americans all Spanish prisoners, including priests, will be put to death, the property of the Church confiscated, and the Protestant religion enforced at the point of the sword. Absurd as this may seem to an American, it is readily believed by the more ignorant subjects of Spain, for the reason that their country has for centuries waged war in just that way. With all due respect to the Roman Catholic religion, it is impossible to speak without condemnation of the Spanish Church as maintained in the Philippine Islands. Nearly $1,500,000 was set apart in one year for the benefit of the Church and its clergy, all this and much more having been extorted by the Spanish Government in fees, taxes, etc., from the poor, underpaid native toilers, while such public improvements as were absolutely indispensable were grudgingly accorded the munificent sum of $6000. Furthermore, the $1,500,000 given to the clergy and religious societies did not include the amounts paid to the priests for marriages, baptisms, indulgences, scapularies, etc., which are pocketed on the spot, and which amount during the year to a sum equal to that accorded to them by the Government. Considering the extortionate demands of the Church and the Government, and the petty peculations of every member of the Spanish official machine, is it any wonder that the down-trodden natives have rebelled at last against the rule of despotic and uncivilized Spain?

The Manila newspapers which, like everything else, are controlled by the Government, publish sensational stories about the "Yankee pigs" and the injuries they are supposed to have received in the battle of May 1st. Admiral Dewey is taking every precaution for the safety and welfare of his sailors. He has given orders that Cavité, now occupied chiefly by the insurgents and refugees, be made as sanitary as possible, and while a few cases of measles have broken out, as a rule the health of all is good. In the tropics measles is not the trifling infantile disease which it is in temperate climates, for here it ranks with smallpox and cholera in the estimation of the quarantine authorities, who will not open a port to any ship having a case of measles on board. This disease, which the inhabitants of a colder climate take little pains to avoid, and place in the same category with whooping-cough and other diseases of infancy, is so contagious in these islands and the percentage of death among its victims is so great, that a few cases among our soldiers would be really a more serious matter than a stranger to these latitudes would be apt to think.

The physicians accompanying the American troops to the Philippines may be called upon to treat several diseases with which they have had a very limited experience, or no experience at all. Among these may be mentioned what is called tropical abscess of the liver, elephantiasis, beriberi, etc. The former is not very common but is often fatal, the prognosis depending principally on the direction in which the abscess ruptures. Elephantiasis is encountered in its most virulent form. I have only seen one case of this and the victim was a most revolting object. Beriberi I have discussed pretty thoroughly in a previous letter. All of these diseases are more common among the natives than among the European

population, possibly because the latter are generally more cleanly than their darker-skinned neighbors.

These natives are very interesting, regarded from almost any standpoint, and some of their beliefs and customs must have come down to them from remote antiquity. There is an old idea, common to the people of many different races, that contact with a person's perspiration may excite the most passionate love. The attempt to attract a person of the opposite sex by means of the perspiration probably gave rise to a curious custom which prevails among the Philippinos. When two young people who are engaged to be married are compelled to separate for a time, they exchange articles of clothing, each believing that thus the faithfulness of the absent one will be assured. These articles are carefully treasured, being kissed and smelled of whenever an opportunity offers, and, whether by reason of some magnetic property with which the clothing of the person may have been endowed or by the odor of the perspiration as supposed, these keepsakes are said rarely to fail in the purpose for which they are given.

In speaking of the natives it is necessary to distinguish the Tagals, who occupy the greater part of Luzon and the smaller islands near by, from the Negritos who are of a much lower order of humanity and on some of the more remote islands are as wild as Hottentots. Stories are told of human sacrifices offered by these people to their heathen gods. Then there are the various tribes in the southern and the extreme northern parts of the archipelago, who are unlike both the Tagals and the Negritos. Each of these tribes has its own language, there being, it is said, as many as twenty different dialects spoken by the various native tribes. The Negritos in Luzon are mostly servants and laborers. These various tribes are of course mixed with each other, and in Manila and vicinity many of the natives have a trace of Spanish blood.

The principal followers of Aguinaldo are the Tagals and mixed descendants of Tagals, Malays, and half-castes, many of whom are well-to-do and a few educated; but the great mass of the population is ignorant and uncivilized and utterly incapable of self-government, not one per cent. of the inhabitants of these islands being able to read. If Aguinaldo thinks that he can form a stable republic out of such material, he is indulging in a wild dream from which he will soon be rudely awakened. The man seems to be quite ignorant of diplomacy, for more than a week ago he had a conference with the German Admiral on board the German flagship. A rupture between the Americans and the Philippinos is evidently what the Germans are trying to bring about; but if Aguinaldo should be so unfortunate as to estrange Admiral Dewey by his unwise actions, he might at once and forever say good by to his schemes for making himself President of the Philippine Republic. The expected arrival of our transports will probably put a new face on the whole matter. If, as we have reason to suppose, the troops are aided by the insurgents, or at least are not opposed by them, the taking of Manila ought to be an easy task. The Spanish are taking great pains to fortify the water front, but very little preparation has been made to ward off a possible attack from the land side. It is to be hoped that the city can be taken by Admiral Dewey and our occupation of the Philippines perfected without sending the troops to fight in the interior, as tropical warfare is something to which our soldiers are quite unaccustomed. A naval victory is one thing and an army victory is quite another. After Dewey had fought the greatest naval battle of modern times, in which he totally annihilated the Spanish fleet, the men on the ships washed their hands and ate their dinner with appetites whetted by the thought that not one comrade had been killed. If a battle of equal importance had been fought in the interior behind Manila, the killed and wounded would have been numbered in the hundreds.

If our soldiers are obliged to march any considerable distance, the dense tropical vegetation, the tough vines and briars will doubtless make their progress very difficult. Then there is the question of water, for the streams in the Philippines are so infested with leeches as to make drinking from them very dangerous. To swallow a leech is a very serious accident and one often followed by hemorrhage from the stomach, pains, and convulsions. It may be remembered that the soldiers in Napoleon's Egyptian campaign frequently swallowed leeches, with very disagreeable, and sometimes fatal, effect.

Soldiering in the Philippines will be accompanied by many inconveniences. Sleeping on the ground is not conducive to peaceful dreams in a country where snakes are as common as they are here and where myriads of tiny worms and insects drop on or crawl over the sleeper, some of the former having a disagreeable habit of crawling into one's ears. The natives have a superstition that the centipede can make its way through the ear until it reaches the brain and causes death. Of course this is not true, but there is no doubt that an insect in the ear may cause excruciating pain. These are only a very few of the many annoyances and dangers which our soldiers will be obliged to endure, and it is to be hoped that whoever has charge of the commissary department of the American Army will make some allowance for the climate and not feed the men on fat bacon three times a day.

CLINICAL MEMORANDUM.

GUNSHOT WOUND OF THE ABDOMEN: TEN INTESTINAL PERFORATIONS AND TWELVE PERFORATIONS OF THE MESENTERY; OPERATION; RECOVERY.

By GEORGE TULLY VAUGHAN, M.D.,
OF WASHINGTON, D. C.:
PASSED-ASSISTANT SURGEON, UNITED STATES MARINE HOSPITAL SERVICE; PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY IN GEORGETOWN UNIVERSITY.

G. A. F., white, male, aged thirty-one years, native of Virginia, was admitted to the Emergency Hospital during the night of May 26, 1898, having just been shot in the abdomen with a pistol. When seen by me, a little more than one hour after the shooting, his condition was very good. Pulse 84; temperature not taken; there was no nausea, vomiting, or evidence of shock; but the patient complained of severe paroxysms of pain in the abdomen. The wound was in the left side of the abdomen, about two centimeters (¾ of an inch) above the center of a line drawn from the navel to the anterior superior spinous process of the ilium, but a little nearer the navel. Blood was oozing steadily from the wound. It was impossible to decide from the symptoms present whether or not the viscera had been injured. Injections per rectum of gas or water were not made use of on account of the danger of forcing intestinal contents into the peritoneal cavity in case the intestine had been wounded. It was thought safer and more satisfactory to explore the wound with probe and finger, enlarging it as might be necessary for this purpose.

The patient having been chloroformed and the surface carefully cleansed as if for abdominal section, attempts were made to introduce a probe into the peritoneal cavity, but the effort failed, probably owing to the muscles having been contracted when perforated, their subsequent relaxation interposing sound tissue across the track of the ball. Accordingly the probe was introduced as deep as it would enter and the tissues were divided to this depth for a space of about six centimeters (2½ inches). The probe was then introduced at a different angle and the tissues again divided, when it was found that the probe entered the peritoneal cavity, its entrance being followed by a free discharge of blood. The incision in the skin and muscles was rapidly extended to about thirteen centimeters (5¼ inches) and the peritoneum incised, blood flowing freely from the cavity.

The first coil of intestine which presented was drawn carefully through the wound and examined. Not more than ten centimeters had been thus drawn out before a perforation was found, there being two openings, one of entrance and the other of exit. These were closed and further search made, the coils of intestine being surrounded by flannel cloths wrung out of hot salt solution and replaced at one end while they were being drawn out at the other. Eight openings were found in what was thought to be the lower part of the jejunum and two in the ileum. There were six perforations of the mesentery, or twelve openings in all, the wounds of entrance and exit in the mesentery being closed separately. The ten perforations of the intestine and twelve of the mesentery made a total of twenty-two openings. Twenty of these openings were closed by sutures; two in the mesentery were not bleeding and were passed over. A round sewing needle with fine silk was used, the mattrass suture introduced including simply the serous and subserous tissues exclusive of mucous membrane, thus approximating the serous surfaces. The line of sutures was transverse to the long axis of the intestine. The wounds in the mesentery were closed in the same way. In a few of the large wounds of the intestine, where the ball had evidently cut through the convex border of the gut, making a single, very ragged, large opening, instead of two small openings, two sets of sutures where used, the first to approximate the edges, and the second, the mattrass suture as already mentioned. In all other places a single row of sutures was used, the threads being placed about half a centimeter apart (five to an inch). The bleeding was chiefly from the mesentery and the vessels were controlled by the sutures. There was about half a pint of blood in the abdominal cavity. The ball, a .38-caliber, was found wrapped in a portion of the great omentum. It was not scarred or flattened, evidently not having struck a bone or other hard object.

Fortunately the portion of intestine wounded, included in a length of about two meters of the jejunum and ileum, was empty of fecal matter and none was detected in the peritoneal cavity; but the cavity was thoroughly irrigated with about 10,000 cubic centimeters of warm salt solution. The entire length of the small intestine was examined by sight and the large intestine, stomach, kidneys, liver, and spleen by palpation. The wound in the abdomen was closed by means of interrupted silkworm-gut sutures, including skin, muscle and peritoneum, without drainage. Pulse 124 at close of the operation, which lasted 2½ hours. The patient suffered considerable pain on recovering from the anesthetic (chloroform) and was given .015 gram (approximately ¼ of a grain) of morphin hypodermatically.

May 27th. Patient slept very little; is nauseated. Ordered sulphate of magnesia, four grams (60 grains) every hour until bowels should act. After taking two ounces the bowels moved four or five times and the nausea and other symptoms improved. Temperature, in axilla, 38° C. (100° F.), both morning and evening. Pulse 120 in morning, 104 in evening. May 28th. Temperature 37.2° C. in morning, 37.4° C. evening. Pulse 104 in morning and evening. May 29th. Temperature 37° C. (98° F.); pulse 80. After this the pulse and temperature were practically normal; once for some unknown reason the temperature rose to 38.8° C. The patient had no opiates after the 29th. June 10th. First dressing; stitches removed. There was primary union throughout except at the point of entrance of the bullet and a short distance below, both of which were covered by small scabs. A few drops of pus exuded where some of the sutures passed through the skin. June 12th. Patient allowed to get up, abdomen being well supported by a flannel bandage. June 19th. Patient walking about; still small scabs over the two points mentioned.

June 24th. Patient well; appetite good, bowels act fairly well, occasionally requiring salts or an enema. Complains of a little stiffness about the wound. Discharged from treatment.

MEDICAL PROGRESS.

Egyptian Medical Tattooing.—FOUQUET (*Centralbl. f. Chir.*, June 25, 1898) found upon the body of a priestess who was embalmed in the 11th Dynasty—about 3000 years B. C.—linear blue marks which he at first supposed were for ornament but which he afterward concluded were the result of some vigorous application of remedies. The marks were both below and above the umbilicus, those below running almost horizontally while those above it ran in a vertical direction. The surgical measures were evidently taken a long time before the death of the woman, and were perhaps intended to cure her of some pelvic trouble, chronic pelvic peritonitis or whatnot. This method of introducing drugs into the body is still practised in Egypt, and the writer was able to collect details of ninety-seven cases in which it was employed. In most of them the tattooing was done upon the temples for the relief of headache or neuralgia, but in other cases the scarification was made upon the hands, feet, shoulders, knees, buttocks, neck, or abdomen. The technic of this treatment is as follows: From three to seven needles, which are bound together in a bunch, are thrust obliquely into the skin. When blood begins to flow from the punctures thus made, a mixture of milk and soot, to which the juice of various plants has been added, is rubbed into the wounds.

A New Method of Disinfecting Rooms with Formalin.—SCHLOSSMANN (*Berlin. Klin. Wochenschr.*, June 20, 1898) describes an apparatus for the disinfection of rooms by formalin, which he and WALTHER have devised, and which gives a far more perfect disinfection and in a much shorter time than any apparatus yet brought forward. Steam from a kettle of boiling water passes into the reservoir full of a mixture of ten parts of forty-per-cent. formaldehyd (formalin) and one part glycerin. From this reservoir through four escape pipes there passes off a vapor composed of formalin, glycerin, and water. Ten minutes after the apparatus is set going in a room 16x14x10 feet the fog is so dense that it is impossible to determine if an incandescent lamp in the center of the room is lighted. In less than three hours all germs of whatever sort that were in the room will have been killed. The advantages claimed for this method of using formalin are.

1. Absolute sterilization.

2. It is not necessary to paste up tight the windows and doors; on the contrary a little draft is of benefit.

3. The apparatus is so constructed that it produces currents of air and so insures the sterilization of all the air in the room.

4. The maximum time required is three hours, as compared to twenty-four hours required by the Trillat or Schering methods.

5. The apparatus, which is made by Lingner of Dresden, costs little to operate; and like other formalin methods of disinfection it possesses the advantage that all articles may be left in the room without fear of injury.

6. It is easy to use and as it never has a pressure of more than half an atmosphere there is no danger of an explosion.

7. The fog of glycerin-formaldehyd—a combination which the writers call glycoform—is heavier than the air. By the energy of the apparatus it is driven against the ceiling of the room and then sinks slowly to the ground, bringing with it mechanically all the germs in the air.

8. The disinfecting power of the apparatus is only limited by the penetrating power of the gas. Wherever the gas penetrates so far will there be sterilization.

At the end of the disinfection the windows are opened and the room is aired. Enough ammonia is sprinkled about to neutralize the smell of the formaldehyd, and in a short time the room is absolutely odorless. The method is simple enough to one who understands it, but it is better for the sake of thoroughness that it should not be turned over to the hands of the householder, but should be carried out by some one who has had special instruction in the method.

A Comparison between Dry and Moist Thiersch Grafts.—ENDERLEN (*Deut. Zeitschr. f. Chir.*, vol. 48, p. 1) has experimented with Thiersch grafts in order to test their vitality and power of growth after they have been dried for a number of days. He found that they would adhere when planted, and grow, although they had been preserved dry for several days in Petri dishes, but their growth under such circumstances was by no means as active as that of fresh grafts, or of those which had been kept for a like time in sterile salt solution. As the centers of grafts which are kept in a dry state for three or four days are not yet entirely dry, it is scarcely fair to say that dried grafts will grow. Those which were quite dry and hard did not in any case show signs of cell multiplication. Grafts prepared according to the rules laid down by Thiersch adhered better and grew faster than those prepared according to Krause's method, or in long strips. The writer says that the growth of epithelium from sweat-glands is very apt to lead one into error as to the power of growth of a graft. In his preservation experiments he found that the epithelium is much more enduring than the cutis, which goes to pieces in four days or less, even though it be preserved in a moist condition.

Pelvic Examination in an Inclined Position.—JAYLE (*La Presse Med.*, June 22, 1898) says that there are great advantages to be gained in the examination of difficult gynecologic cases from an inverted inclined position of the patient. This position is essentially that known as Trendelenburg's except that the patient instead of hanging by her knees, rests with her shoulders against two blocks, while the head is raised upon a cushion. This avoids the unpleasant rush of blood to the head, and at the same time it leaves the pelvis free from any strain and easily movable as the examiner may desire.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

SATURDAY, JULY 23, 1898.

YELLOW FEVER AMONG THE TROOPS.

THE dread news that the scourge, yellow fever, has invaded the army at Santiago has been received. This, indeed, was expected, and occasions no surprise, neither should it cause panic nor serious alarm. Now that the trenches are no longer occupied an epidemic among the American soldiers is not to be feared. Thus far, the number of cases is limited and the nature of the disease is mild.

British experience in Jamaica has demonstrated the possibility of rendering a garrison, stationed in the tropics, comparatively free from yellow fever. This has been accomplished by removing the camp from the immediate vicinity of the coast towns, and locating the station at as high a level as can be conveniently reached, providing the camp with an abundant supply of good water, and prohibiting intercourse with the native population. It is true that the circumstances attending the Santiago invasion have been such as to contribute, in the fullest degree, to sickness among the troops. The army has been obliged to fight its way through jungle, rain, and mud, and to endure the terrific nervous strain of lying upon its arms for days together, in the face of the enemy, with the hourly expectation of an assault. Such conditions could not have been endured long beneath the sweltering rays of a tropical sun, without widespread and disastrous consequences. Capitulation has come none too soon. A most important factor of the surrender, however, is not the number of prisoners taken, nor the number of arms given up, but the opportunity thus afforded (1) to get the American soldiers out of the trenches and establish a permanent camp on some lofty, accessible plateau, where the water-supply shall be abundant and the drainage good; (2) to secure a similar temporary camp for the prisoners of war; and (3) to segregate the refugees and prevent the possibility of contamination by them. In the meantime, the sick can be carefully isolated and provided with the necessary care and attendance. As Surgeon-Major Summers aptly remarks, "The best possible place to treat yellow fever is a military camp, and the best military camp in the world in which to treat the disease is a United States Army camp."

The type of yellow fever which is indigenous to the eastern part of Cuba is mild and easily controlled by well-known methods, if promptly and efficiently applied. That the very best means of dealing with this disease will be at hand and energetically applied we have every reason to believe. The Surgeon General's department has for years made a careful study of yellow fever; the army is under the immediate care of a score of surgeons, skilled by practical experience in dealing with the disease, and these are supplemented by assistants who, during the past few months, have been carefully instructed in the nature of tropical diseases and all that pertains to their treatment, prevention, and control. Whatever want of preparation then may be justly charged against other departments of the army, happily the medical service finds itself ready to cope with this emergency.

The present is no time for experimentation, but the application of well-known hygienic and sanitary principles can be relied upon to protect the soldier, not only from the invasion of the disease, but from its ravages when it has finally appeared. Sanarelli's serum has not yet been sufficiently tried in the demonstration of its freedom from danger as a prophylactic, to subject any large body of men to its application, nor have its curative properties been found so efficacious as to justify an exclusive dependence upon it as a therapeutic agent.

ADVANCES IN MEDICAL EDUCATION

THE change from a proprietary medical college to a medical department of an established university is regarded as a movement toward higher education The predominating personal interest of the faculty is thereby subordinated to the interests of medical education. The public contributes pecuniary assistance more freely, and the equipment and facilities necessary to reach the highest standard are thereby assured.

In New York during the past few months two schools have thus allied themselves with established universities, and it is with no little interest that the medical fraternity is watching the evolution of their plans along these higher lines of medical equipment as well as the broadening influences of the new alliances. One feature that seems to be characteristic of both institutions is an unbounded enlargement of the teaching staff. The advance sheets of the University Bellevue Medical College presents an array of ninety-seven men in its faculty and staff, while the Cornell Medical School is reported to have a still greater number. The effort has been to secure men who have hospital appointments or dispensary positions with the evident idea of securing clinical material. The two schools have seemingly been vying with each other in this direction. It is one thing, however, to pass before medical students a large array of clinical material, but quite another to have this material carefully differentiated and effectively presented to the students' mind. How much attention has been directed to selecting men who have talent and experience as teachers can only be known after this staff has become adjusted to its work.

In the Bellevue College the effort has been made to continue its reputation as a school of clinical instruction, and the circular announces that the facil ities for such work will be amply provided by their new building on the corner of First Avenue and Twenty-sixth Street, and the building directly opposite the entrance to Bellevue Hospital.

The laboratory work has been greatly extended both in pathology and bacteriology. Hygiene and sanitation will demand more attention than formerly, and Dr. Doty, the Health-Officer of the Port of New York, will conduct a department in quarantine sanitation. The course of lectures on tropical diseases will doubtless attract men who expect to settle in the South or our newly acquired tropical islands, such as Cuba and the Philippines. This course will be conducted by Dr. J. Edward Stubbert, who has lived for a number of years in the West-Indian Islands and various parts of South America. At the present time he is the resident physician of the Loomis Sanitarium at Liberty, N. Y. Tropical diseases are attracting more and more attention, and it is noticeable that the British Medical Association at its meeting this year has introduced a section devoted exclusively to tropical diseases. This new course established in Bellevue will doubtless prove a popular and valuable innovation.

THE TAXATION OF MEDICINAL PREPARATIONS.

THE principles involved in the new internal revenue law, the passage and enforcement of which has been made necessary in view of the enormous expenditures by the Government in carrying on the conflict with Spain, are upheld by every loyal American, and each will contribute to the income of the National treasury to the extent either of his means or necessities. The question as to whether the construction which will be put upon certain sections of the law will be just and in conformity with the welfare of the people, however, is of vital interest and importance.

Particularly does this refer to that portion of the law relating to the taxation of so-called patent and proprietary medicines, as well as to those prepared by manufacturing chemists the containers of which bear a label specifying the virtues and dosage of the preparation. According to a natural interpretation of this clause every product issued by the manufacturing chemist, practically no matter what its composition or its value in the hands of the physician as a safeguard against disease, will be subject to a tax equal to that levied upon the worthless nostrums with which the country is so completely flooded at all times. There can be no doubt that such an interpretation by the Commissioner of Internal Revenue at Washington would be manifestly unjust, for those preparations which are confessedly designed only for dispensing through the medium of a physician's prescriptions should not be placed in the same category as those widely advertised in the daily press and sold to any applicant over the retail druggist's counter.

It has been argued that the tax is so small that it can be met by the manufacturer almost without inconvenience, and that his loyalty to his country should deter him from seeking to be made exempt from contributing his just share to that country's needs, but be this as it may, the poor as well as the rich must at times have recourse to the use of standard medicinal agents for the alleviation of human ills, and, viewing the matter in a practical every-day light, it is hardly to be supposed that the manufacturing chemist, any more than the brewer or the importer of table waters, in the end will be the one to defray the additional cost of putting his products on the market.

The opinion is very general that manufacturers of patent or proprietary medicines reap very large profits from the sale of their goods and there can be no doubt that it was the intention of Congress, in framing the act, to reach this class of articles rather than those put forth by the manufacturing chemist for use through the agency of the physician. The Internal Revenue Act of 1864 accomplished this purpose. The injustice of laying additional burdens upon the sick poor is so apparent that nothing but the clearest proof that such was the intention of Congress will justify those entrusted with the interpretation of the act in giving it such an effect.

The language of Schedule B of the Act reads as follows: "All medicinal preparations or compositions whatsoever made and sold or removed for sale by any person or persons whatever, wherein the person making or preparing the same has or claims to have any private formula, secret or occult art for the making or preparing of the same, or which are prepared, uttered, vended or exposed for sale under any letter patent *or trademark* or *which are prepared by any formula, published or unpublished;* or held out or recommended to the public by the makers, vendors or proprietors thereof as proprietary medicines *or medicinal proprietary articles or preparations*, or as remedies or specifics for any disease or diseases or affection whatever affecting the human or animal body."

The language used, particularly when read in the light of the caption of the schedule ("Medicinal Proprietary Articles and Preparations") can by no possibility be extended to cover anything except patented, trademarked, or proprietary articles.

Furthermore, the law reads: "The stamp tax provided for in Schedule B of this act shall apply to all medicinal articles compounded by any formula, published or unpublished, which are put up in style or manner similar to that of patent, trademarked, or proprietary medicine in general, or which are advertised on the package or otherwise as remedies or specifics for any ailment, or as having any special claim to merit, or to any peculiar advantage in mode of preparation, quality, use, or effect." This section is also adapted from the law of 1864, but it was never claimed that the provisions of the old act applied in any respect whatever to standard pharmaceutical drugs and preparations. In this adaptation on the part of Congress the word "proprietary" has been omitted, undoubtedly for the purpose of enlarging the scope of the section so as to include what is technically known as non-secret medicines, which are medicines of the same character and class as proprietary medicines, except that the formula is not concealed; but the language used, under any canons of construction, cannot be considered as going beyond that point. In order that standard pharmaceutical preparations should be considered within the scope of this section of the law, the preparations must be put up in a form adapted for the use of the consumer without the intervention of druggist or physician, and the claims made for it must be such as to induce the individual to resort to it to cure him of his ailments.

When he finally announces his decision it undoubtedly will be found that the Commissioner has drawn a line which overlaps on one side or the other the fine distinction so important in such a case, but if it leans in the direction which common humanity dictates, the interests of the manufacturing chemist not entering into the matter, no medicinal preparation designed to assist the reputable physician in his unceasing effort to subjugate disease will be made to add its quota to the National funds collected for the purpose of subjugating the Dons.

ECHOES AND NEWS.

Women Excluded from the Study of Medicine.—The German Medical Association, numbering more than 15,000 members, at its recent conference at Wiesbaden, unanimously adopted a resolution expressing disapproval of the admission of women to the study of medicine.

A Chair of Nursing Established in a Medical School —The

medical department of the University of Texas has taken the lead in officially recognizing the department of nursing in its curriculum. It is reported that Miss Hannah Kindbom has been elected Professor of Nursing at that institution. Professor Kindbom is twenty-six years of age, and a Swede by birth.

The Investigation of the New York Post-Graduate Hospital Concluded.—The special committee of the State Board of Charities appointed to investigate the charges of irregularity in the administration of affairs in the New York Post-Graduate Medical School and Hospital, reports that the charges which it had under consideration were not sustained by the evidence presented.

A Bale of Cotton for the Hospital Fund.—The first bale of cotton of the crop of 1898 has been sent to President McKinley by the citizens of New Orleans as a contribution to the United States Hospital Fund. It was sold at public auction at noon, on Wednesday of last week, from the steps of the Cotton Exchange Building at New York, and the proceeds deposited to the hospital account.

Prehistoric Surgical Instruments.—In a Roman hospital recently excavated at Baden, Switzerland, many medical utensils and surgical instruments were found, among them, probes, tubes, pincers, cauterizing instruments, safety-pins, bone medicine spoons, silver measuring vessels, jars and pots for medicine—some containing traces of ointment. Fourteen rooms of the building have been excavated.

Athletic Training of Soldiers.—The capture of blockhouses, after hard fighting with the Spaniards in the campaign before Santiago, has demonstrated the advantage of athletic training in all military organizations. A member of the 71st New York, in a recent letter home, announces that, "Had it not been that quite a number of us had had thorough athletic training, we could never have endured the terrific assault up those steep hills."

Firing on the Wounded.—The reports that the Spanish sharpshooters deliberately fired on the hospital flag, on the field of El Caney, seems hardly credible. It is true that two of a hospital party were killed, and it is stated that three wounded soldiers, while being carried in litters, were shot and killed. It must be remembered, however, that the lines of battle were very close, and that, with the long-range weapons in use at the present time, missiles seek out unintended victims.

Lady Salisbury Subjected to a Surgical Operation.—It is reported from London that the wife of the Prime Minister has long been afflicted with dropsy and recently submitted to a critical surgical operation for its relief. The cause of the dropsy, and the nature of the operation are not stated. Six doctors assisted at the procedure, including Sir William H. Broadbent, Physician in Ordinary to the Prince of Wales, and Dr. Charles Theodore Williams, Physician Extraordinary to the Queen.

The Requirements of Surgeons in the Volunteer Army.—Surgeon-General Sternberg has recommended, and Secretary Alger has approved, an arrangement by which physicians, appointed by the Governors of States to positions in the volunteer regiments, may be examined by a board of three physicians, appointed by the respective Governors. A certificate of this board—that the candidate has passed a successful physical and professional examination—will be accepted by the War Department as evidence of fitness.

Cubans Donate a Hospital at Key West.—In addition to the many testimonials of appreciation of the interference of the United States in their behalf, which the Cubans have given from time to time, they have recently contributed to the United States Government, a building for hospital purposes. The San Carlos theater and club-house at Key West has been formally ceded by the Cuban owners and stockholders to the Government as a hospital, although they placed no restrictions upon the uses to which the building shall be put.

Legislative Measures for an Increase of Population.—The example set by France in instituting measures for an increase of its population is being followed by Bulgaria. For every son born, beyond a minimum number, twenty francs will be paid, not only to the father, but also to the mother. A soldier who becomes the father of twelve sons will receive a pension large enough to support him, besides a decoration. The same reward will be accorded to his wife. It is gratifying to note that the wife's part in this duty to the State is meeting with adequate recognition.

The Fate of the Reconcentrados.—At the beginning of hostilities, the feature of the war, which appealed to the hearts of Americans was the relief of the Reconcentrados. Recent reports from Cuba seem to indicate that this factor has been almost completely eliminated. Nearly ninety per cent. of those who had been forced into the larger cities at the time of the Maine disaster have died of famine and exposure. In round numbers this includes nearly a million of women, children, and old men. The remaining few who, since the revocation of the order of concentration, have returned to the country, have been able to eke out a miserable existence by means of the wild fruits of the country.

Death under Chloroform.—A fatal accident from the use of chloroform recently occurred at the Infirmary in Edinburgh. The victim was a man who was being anesthetized for the purpose of reducing the dislocation of one of his finger-joints. The history of the case states that, after the first inhalations, the patient began to shout loudly, kick about, and fight, and it required the force of four or five doctors to hold him. This is the usual history of fatal cases, and teaches the importance of recognizing the fact that restlessness on the part of the patient is a protest against too concentrated anesthesia, and when force is resorted to and the anesthetic crowded, this unfortunate condition is aggravated to a fatal termination.

Restrictive Effects of War Taxes.—The New York statutes allow the employment of children between the

ages of twelve and fourteen at remunerative labor during school vacation. Children thus seeking employment are obliged first to secure a certificate from the Board of Health. Under the provisions of the War Revenue Bill, imposing a tax upon "certificates," each child procuring a certificate is obliged to pay a tax of 10 cents. The President of the New York Board of Health has written to the Attorney-General of the United States, calling attention to the fact that, under these conditions, hosts of poor children are deprived of their accustomed privileges. He asks for a ruling upon the particular section of the law which works these hardships, praying for its modification.

A Notorious Offender Convicted.—The difficulty of bringing to account the parasites of the profession who make their livelihood out of unholy and criminal practices, and who unblushingly vaunt their financial success in the face of the world, has been experienced in all communities. It was with satisfaction that we chronicled not long since the success of the New York County Medical Society in ridding New York City of its most persistent offender in this line. After a protracted trial, a notorious specimen of the genus above referred to and a great favorite among the "smart set" in London, has been found guilty, and condemned to seven years of penal servitude. *The* (London) *Times*, in commenting on the rottenness of society morals, says: "Soon after the offender's imprisonment a lady was asked what she and her friends would do now that his services were no longer available. 'Oh,' she replied, 'We have found another man.'"

The Social Position of an M. D. in England.—The medical press deplores the fact that in Great Britain the doctor is too often relegated to an inferior social rank and surroundings, not being admitted to the circle to which the parson, the local banker, the military officer, and the resident lawyer are welcome. This apparently accepted social inferiority of the general practitioner is attributed (1) to the bill-running system which prevails among them; (2) to the intimate association of medicine dispensing (for profit) with general medical practice. As a remedy for this state of affairs a cash system of payment is recommended, and the abolition of the practice of combining the medical and pharmaceutical functions. It is difficult for an American to understand how such simple prejudices should relegate a member of the learned profession to the social rank of trades people, and we are glad to know that the medical profession is gradually receiving in England the social recognition which it deserves.

The Rainfall in Cuba.—The Juragua Iron Company, through its Secretary and Treasurer, Mr. Josiah Monroe, has kept careful weather observations at Firmeza, the mining village of the company, which is located about sixteen miles east of the city of Santiago de Cuba and about five miles inland from the sea, among the mountains, about five hundred feet above sea level. In a recent communication to Surgeon-General Wyman of the Marine Hospital Service, Mr. Monroe gives a detailed tabular account of the temperature, the rainfall, sunshiny days, and cloudy days during the period of 1889-1897. From this we learn that in the year 1889 the rainfall was 76.75 inches; in 1890, 55.84 inches; in 1891, 60.14 inches; in 1892, 51.15; in 1893, 60.53 inches; in 1894, 56.24 inches; in 1895, 63.42 inches; in 1896, 58.22 inches, and in 1897, 90.57 inches. Bright, sunshiny weather is evidently the prevailing condition, the clear days each month throughout this series of years, varying from fourteen to thirty, with the large preponderance in favor of sunshine. The mean daily temperature is very even throughout the year, varying within the narrow limits of 76 to 84 degrees. The hottest period is the middle of the day. The nights are cool. The extent of the downpour when it does rain is illustrated by the fact that in one day, October 20, 1897, there was a rainfall of 14 inches.

CORRESPONDENCE.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

DIPHTHERIA ANTITOXIN STATISTICS ONCE MORE—SOME OPPOSITION MANIFESTING ITSELF TO SERUM-THERAPY—INOCULATIONS FOR RINDERPEST AND THEIR RESULTS—BACTERIOLOGY BEYOND THE DOMAIN OF THE MICROSCOPE—WANDERING AFRICANS AND PATHOLOGIC CURIOSITIES—FILARIA MEDINENSIS.

BERLIN, July 10, 1898.

A DISCUSSION as to the value of diphtheria serum in which Dr. Rassowitz, in the Vienna Medical Association, declared the value attributed to the antitoxin exaggerated, and supported his assertion by recent statistics, has attracted a good deal of attention in the German medical world. Rassowitz's article on the subject has just appeared in Liebreich's *Therapeutische Monatshefte*. As Liebreich, who is the Professor of Pharmacology at the University of Berlin, is known to be opposed to serum-therapy on principle, his opposition having given rise to a warm discussion between himself and Behring two years ago at the German Congress for Internal Medicine, the recent publication would seem to bear the stamp of quasi formal recognition by the school opposed to antitoxic treatment.

In the discussion at Vienna some things came up that are not included in this article. For instance, the reports of the early investigators of the diphtheria antitoxin were the subject of especially trenchant criticism. Just as soon as the serum treatment was introduced the most surprising and gratifying therapeutic effects were reported from it twenty-four to forty-eight hours after an injection. All symptoms had disappeared, the membrane had dropped off, the temperature had fallen, the child had regained its appetite, and a sense of well being replaced the lethargic prostration in many cases. It was these reports that led to the rapid introduction of the remedy.

Now that more is known of antitoxic values and the estimation of the value of serum in protective and curative units has become possible, these early results are open

to most damaging criticism. The number of antitoxic units employed at first was so small that they must have had practically no effect, and the good results reported at first were due entirely to what we now know to be only expectant treatment.

The statistics quoted by Rassowitz are those of St. Petersburg, on which he lays a good deal of stress, and of Trieste, of Basel, and of London. If statistics ever mean anything, perhaps they serve to show that antitoxin is not an infallible remedy for diphtheria when injected on the fifth day of the disease. As Professor Baginsky states in an article that will appear in the *Berliner Klinische Wochenschrift* within the next couple of weeks, there may be in local conditions in other cities, as there undoubtedly has been in London, some reason why antitoxic statistics should not be favorable. The want of official regulation of the antitoxic unit value of serum in England led to the putting on the market of a lot of serum of extremely low antitoxic value, as the *Lancet* examinations showed. The results attained in cases treated with this serum cannot reasonably be said to be the results of serum-therapy.

There is, perhaps, another thing that the unfavorable statistics serve to show, and that is that there are in all epidemics of diphtheria certain fulminant cases of the disease where toxin production is so rapid or its effect so serious that antitoxin does not seem to affect them. There would seem to be more of such cases occurring this year in Germany than for some years. While at Jena I heard Professor Krehl lament the failure of antitoxin in several cases, though it had been employed early in the disease. Here in Berlin there have been a number of such cases this spring.

The exaggerated claims made for the serum as to its effectiveness in *all* cases has undoubtedly led to a certain reaction of opinion, and one is a little surprised to find how many *doctors* have a certain sympathy with the opposition under these circumstances. "Not that we do not think serum-therapy of great benefit," as a prominent director of a large hospital said, "but that we do not think it the universal savior some too devoted adherents have been lauding it to be."

An article from Dr. Kolle, Koch's assistant in South Africa, in the last number of the *Deutsche Medicinische Wochenschrift*, gives the results so far of the forms of immunization introduced by Koch for protection against rinderpest. He says that it is the generally accepted opinion in South Africa that the original immunizing injections of bile introduced by Koch not long after his arrival in South Africa, saved the lives of 2,000,000 head of cattle, as the plague was raging furiously when he arrived. Immunity thus obtained, however, only lasts for from two to four months. It does not begin to protect for some time after the injections are begun, and besides is expensive, costing the lives of five out of every hundred cattle.

Though the bacterial cause of the disease remains unknown, an antitoxic serum has been found that furnishes lasting immunity, at least as far as observations go. It has been tried on 100,000 cases satisfactorily, and it has been found that sheep may be used to furnish the serum if inoculated five or six days before immunizing serum is desired with 50 to 100 cubic centimeters of virulent blood. In this way the dangers of conveying such diseases as Texas fever, anthrax, or tuberculosis, so common in cattle in South Africa, is avoided.

Though the smallest drop of an infected animal's blood conveys the infection, the microbic cause has not been found. Dr. Kolle thinks that the reason is that the microbe is too small to be seen with the present powers of the microscope. According to Abbe's researches, a microbe less than one-third the size of Pfeiffer's influenza bacillus would be invisible under the microscope. Kolle does not think that the bacterial cause of cattle plague can be much smaller than this, because, unlike Loeffler's experience with foot and mouth disease, the infectious material will not pass through a filter.

Three very interesting, exceedingly minute organisms are exciting the deepest interest of the world's greatest bacteriologists just now. At Paris Metchnikoff, Roux, and Nocard are studying what they think is the cause of pleuropneumonia in cattle, and it presents itself as a microbe so small that it is only discoverable because it produces clouding in culture media, and is seen under the microscope as minute points in the culture medium that strongly refract light and so become visible. Loeffler believes that the cause of foot and mouth disease is organic, despite its passage through a filter, for it has the quality of increasing itself after inoculation. Finally, what is this organism of cattle plague that has occupied Koch so? It would seem with this array of talent devoted to one subject the technic for ultra-microscopic bacteriology must be materially advanced in the near future.

Apropos of Koch's lecture on malaria and Texas fever, it is a little surprising to note the *British Medical Journal's* editorial on honor to whom it is due. The false impression that suggested the expression of editorial opinion was due to an incomplete report of what Koch said. As I reported at the time, his acknowledgment of the work done by Dr. Allen J. Smith, Professor of Pathology in the University of Texas, in Texas fever was most complete. He fully detailed Professor Smith's observations on the infectiveness of young ticks that had never been on infected cattle, and then described his own substantiation of them. A number of Americans who were present exchanged significant looks of compatriotic feeling. That the English workers on the mosquito theory of malaria were not mentioned by name is due, I suppose, to the fact that here in Germany the subject is not considered as yet to have gotten beyond the stage of merest theory.

The troupe of Toga negroes from the German colony in East Africa, which has been on exhibition at one of the cheap museums in Berlin, has furnished Berlin doctors with some rare opportunities for the study of unusual diseases. In the blood of some of them certain of the special tropical forms of the malarial parasite were found. A number of them developed smallpox, and gave the opportunity so rare here on the Continent of studying the appearance of the eruption on black skins, and now one of them has proved to have that rare parasite, the *filaria*

medinensis, or *dracunculus medinensis*. What looked like an ordinary leg ulcer refused to heal for some time, and at length a portion of a worm was noticed protruding from it. Each day 1½ to 3 centimeters more of the worm has come out, until now some 30 centimeters in all has been protruded. The Africans themselves take cold baths, which are thought to favor the exit of the worm once it starts to come out, and twist the amount of worm which appears each day on a small piece of stick to keep it from going back. This is the only treatment that is employed in this case, so that the thoroughgoing eclecticism of the Berlin school, even as regards the adoption of popular remedies, is evident. Every precaution is taken not to injure or rupture the worm, as that accident is often followed by serious infection of the parts. This infection is liable to invade the whole extent of the subcutaneous tissue in which the worm has its habitat, and as the worm may reach the length of even a meter (forty inches), serious cellulitis, that may require amputation, or may spread upward to the body and kill the patient, may occur. Another of the Africans is being treated for an ulcer near a malleolus that it is thought may prove to be also filarial in origin, the parasite just approaching the surface.

Paris.

WHEN SHOULD A KIDNEY BE REMOVED FOR HEMORRHAGE?—TORSION OF THE ENTIRE SMALL INTESTINE—CHOLEDOCHOTOMY WITH DRAINAGE BUT NO SUTURE—TREATMENT OF SIMPLE ULCER OF THE STOMACH—CARPUS CURVUS—SWELLING OF THE PAROTID GLANDS AFTER THE APPLICATION OF TINCTURE OF IODIN.

POUSSON spoke of a case of nephrectomy for renal hemorrhage before the the Surgical Society, June 1st. The patient was a woman, and the source of the bleeding having been determined by cystoscopic examination, the operator at first performed nephrotomy, but finding no cause for the hemorrhage, he therefore removed the kidney. There were several ecchymoses in its pelvis and different parts of the organ were congested and sclerotic, but there was no evidence of stone or tuberculosis. Six months later the patient was free from further hemorrhage.

POIRIER reported a similar case occurring in a man aged forty-eight years, whose kidney he had removed for hemorrhage, although nothing except a certain amount of chronic inflammatiou could be found in it. The patient recovered from the operation, but died some six weeks later from a pulmonary trouble. The speaker said that to his mind it was not clear that a kidney should be removed under such circumstances.

At the meeting of June 8th, POTHERAT strongly objected to a nephrectomy for so slight a cause. He treated for eighteen months for hematuria a woman whose right kidney was displaced, enlarged, and nodular, and clearly the source of the hemorrhages. Thinking that a neoplasm existed, although there was a small amount of albumin in the urine, he decided to removed the organ. It was both large and irregular, but when opened contained no calculus, nor was there any evidence of a neoplasm. For four days there was almost complete anuria, which was only temporarily relieved by the administration of theobromin, and the patient died some days later with uremic symptoms. The kidney which had been removed was simply hypertrophied as compensatory to the other one which was badly sclerosed. Another patient who had been troubled for three months with hemorrhage cystoscopically shown to come from the right ureter, had tenderness over the right kidney. Mindful of his previous unfortunate experience, Potherat decided not to remove the kidney until he had positive proof that it was abnormal. Attempts were therefore made to catheterize the ureter, but they failed in that the catheter could be passed only some millimeters beyond the orifice. From that time on the hemorrhages ceased, and had not recurred at the date of report, some two months later.

DELBET described torsion of the whole small intestine, an accident which is little known, but which he had twice observed. In the first instance the cause of the intestinal obstruction was not made out and an entero-anastomosis was performed. The patient died and at autopsy the real condition of affairs was made out. The mesentery was twisted in the direction of the hands of a watch. A second case occurring in a man aged sixty-seven years, was accurately diagnosed and the twist was unwound. Here too the twist was in the direction above mentioned. The result of operation was most favorable, and the following day the patient had a natural movement of the bowels. Unfortunately a bronchopneumonia followed the operation from which he died on the eleventh day.

QUENU recited two cases of choledochotomy, the first performed upon a woman aged fifty who in addition to her jaundice had advanced cardiac lesions, ascites, and a moderate glycosuria. The operation itself was rendered more difficult by the hypertrophy of the liver, and the extensive adhesions about the common duct, which made it impossible to do more than blindly divide the tissues at the tip of the finger. The stone was, however, removed without accident, but it would have been impossible to have sewed up the incision, even if this had been a step in the operation which Quenu deems inadvisable. The jaundice cleared up rapidly but the fistula did not close for two months. An attempt made with a probe to determine the patulous condition of the common duct, provoked so severe a hemorrhage that the operator thought that he had opened the portal vein. The cirrhosis of the liver and the cardiac complications persisted as the operation was performed too late to restore their integrity altogether. A second patient, also a woman, had been ill for more than three years with attacks of pain, fever, vomiting, etc., with continuous jaundice. Here too the adhesions were firm, the transverse colon, omentum, stomach, and duodenum being glued together and to the biliary passages in a way that defied dissection. The stone was at last exposed by a slow scratching process. It was large and pear-shaped, and might have been thought to lie in the gall-bladder, were it not that its point

was upward, and not downward as is the case in the pear-shaped calculi of the gall-bladder. In both of these cases the parts in the vicinity were so arranged after operation as to make a funnel from the opening in the common duct to the wound in the skin, and in this a drain was placed. In neither was there any peritonitis, although the bile was presumably septic. The fistula in the second case closed in twenty days. These cases prove the success which attends the open treatment of the wound in the common duct. In both patients moreover the bile in the urine persisted after the jaundice had entirely disappeared, which fact led Quenu to the conclusion that there existed higher up in the biliary passages secondary obstructions of a minute character.

At the Therapeutic Society, May 25th, MATHIEU said that in the treatment of simple ulcer of the stomach preparations of iron, such as the perchlorid, and arsenic ought never to be given as they increase the hyperacidity and the interstitial gastritis, and so delay the cicatrization of the ulcer. The true treatment consists in the repose of the stomach, as complete as possible, which is best secured by rectal alimentation. The use of the sound either for the introduction of bismuth or other remedies, or for the sake of testing the contents of the stomach, is a dangerous practice, as it may bring on an alarming hemorrhage. The use of alkalies to counteract the acidity of the organ has been highly spoken of, but they act by increasing the motor activity of the stomach, and so their use may be attended with danger. Surgical measures are a hopeless risk, as in nearly every case it is impossible to find the point of the hemorrhage.

At the Academy of Medicine DELBET described *carpus curvus*, an affection about which there is very little general knowledge. The hand in this trouble while preserving its normal form is displaced forward as if a luxation of the carpus existed. The plane of the posterior surface of the forearm, if continued downward, would pass quite behind the carpus and metacarpus. The plane of the anterior surface of the forearm, on the contrary, would cut the carpus and leave most of the hand anterior to it. The hand is also displaced toward the ulnar side, so that the axis of the forearm instead of falling through the head of the third metacarpal, falls nearly or quite through that of the second. Dissection of this deformity shows that it is due to a curving of the radius, with a secondary luxation at the ulnocarpal joint, a true deformity of growth, similar to that seen in genu valgum. If the case is sufficiently severe to require operation, a good result may be obtained by an accurate division of the radius.

At the Medical Society of the Hospitals, June 3d, RENON described a double parotiditis which followed the application of the tincture of iodin. The patient was a man, aged fifty-one years, whose chest had been painted with iodin for a cough. The following day the skin of the chest was edematous and painful, and the same day the right parotid gland swelled, the other one being affected in like manner the succeeding day. In the opinion of the writer the unhealthy state of the buccal mucous membrane aided in the swelling of the glands. The swelling subsided in a few days.

LE GENDRE had noticed that the extensive application of the tincture of iodin upon rheumatic joints is sometimes followed by a tenderness of the parotid glands.

MUCOUS MEMBRANE ERUPTION IN MEASLES.

To the Editor of the MEDICAL NEWS.

DEAR SIR: In your issue of the 25th ult., page 818, I note with some surprise that an eruption upon the mucous surfaces of the mouth in the earlier stages of measles is regarded as a new diagnostic sign, for the discovery of which, it is said, we are indebted to Koplik of New York.

For more than fifteen years I have noticed that the buccal and faucial mucous membrane usually presents the papular eruption incident to measles from twenty-four to forty-eight hours prior to the development of the cutaneous eruption. In cases of suspected measles I have always inspected the mouth and pharynx in search of the mucous papules and in many instances I have, by their presence, been enabled to diagnosticate the disease some hours in advance of the appearance of the skin eruption. This eruption is an almost constant precursor of the cutaneous eruption and is fully as reliable a sign as the latter. I have noticed these "spots" most often upon the soft palate. I do not regard the eruption as a new sign of measles for I believe that many physicians have made use of it as an early aid to diagnosis. I recall instances where "old grannies" have made use of this "new sign," and it may be that the honor of its discovery belongs to them. Certainly the honor belongs not to any one of the present generation of medical practitioners.

Respectfully,

A. L. HALL, M.D.

FAIR HAVEN, N. Y., July 11, 1898.

SOCIETY PROCEEDINGS.

ILLINOIS STATE MEDICAL SOCIETY.

Forty-Eighth Annual Meeting, Held at Galesburg, Ill., May 17, 18, and 19, 1898.

THE Society met in the Court House, under the presidency of DR. J. M. G. Carter of Waukegan. An address of welcome, delivered by the HON. F. F. COOK, was responded to by the President.

SECTION ON PRACTICE OF MEDICINE.

DR. ARTHUR R. EDWARDS of Chicago in the Chair.

The first paper read in this section was by DR. FRANK P. NORBURY of Jacksonville, entitled

MALNUTRITION IN INFANTS.

The author said that nearly all cases of malnutrition are the result of gastro-intestinal disorders incidental to errors of diet. Over-education of the mother is responsible for her lack of ability to supply wholesome milk to the infant. Again, other conditions, such as excitement, worry, neurasthenia, the occurrence of menstruation, etc., may produce unfavorable results upon the milk,

and thus disturb its nutritive value. Artificial feeding is responsible in many cases for indigestion in infants. This is the result of faulty methods of administration of foods and of the promiscuous and heterogeneous selection of food-stuffs prescribed by the neighbor or parent. The treatment has two main objects in view, namely, to arrest wasting, and to repair the damage done by the disease.

INFANTILE SCURVY, WITH REPORT OF CASES,

was read by DR. ISAAC A. ABT of Chicago. He said the earliest cases reported were erroneously described as cases of acute rachitis. We were indebted to Cheadle of London, who described the disease in detail as infantile scurvy in 1878, and later as osteal or periosteal cachexia with scurvy. The essayist related cases that had come under his observation to illustrate the course of the disease. He discussed both the etiology and symptomatology at length.

The diagnosis in well-marked cases is not difficult. With reference to the differential diagnosis, congenital syphilis can be excluded by the history of the case, and by the absence of syphilitic lesions on the skin and mucous membranes. In congenital syphilis there is never a history of severe pain. The pseudoparalyses of syphilis are limited nearly always to the upper extremities; the swelling is never so intense as in cases of infantile scurvy, and is more prone to occur on the epiphyses than on the diaphyses. Separation of the epiphyses occurs in both diseases. A spinal paralysis may be thought of, although in such cases there is neither tenderness nor swelling. As to the treatment, brilliant results are obtained by providing a suitable diet, such as fresh cow's milk, or mother's milk, beef juice, orange or lemon juice, fresh vegetables, mashed potatoes, etc. The child should be placed under the best possible hygienic conditions; good ventilation should be provided for, and under favorable conditions of weather the child should be out of doors. Cod-liver oil by mouth or inunction is especially indicated when the child recovers from the scorbutic condition in order to aid nutrition.

DR. FRANK S. CHURCHILL of Chicago followed with a paper on

MODIFIED MILK.

He discussed the laboratory method and home modifications of milk.

THE DIAGNOSIS OF PLEURISY WITH EFFUSION, WITH ESPECIAL REFERENCE TO MISLEADING PHYSICAL SIGNS,

was the title of a paper by DR. JAMES B. HERRICK of Chicago. He first spoke of the importance of careful inquiry into the history of the patient, and dwelt upon the fact that in some instances there may be an absence of pain and cough, the clinical symptoms resembling those of mild typhoid fever. In other cases the severity of the symptoms and the explosive onset will remind one of pneumonia. Among the signs which may mislead, he mentioned the occasional inspiratory recession of interspaces and the decubitus upon the sound side. He regarded vocal fremitus as of relatively inferior value because of the many conditions which may cause it to be retained even though there is a large amount of fluid present. With small amounts of fluid a careful examination should be made in the posterior axillary line just external to the angle of the scapula, for signs are often present here though absent elsewhere. Even with quite large effusions there is a triangular area of relative dulness above the line of flatness posteriorly. Quite pronounced bronchial breathing and well transmitted voice sounds can frequently be heard at this point.

The crucial test is exploratory puncture. With careful asepsis and a knowledge of the anatomy of the thoracic viscera there is practically no danger in this procedure. Negative results should not lead to the exclusion of pleurisy with effusion until circumscribed collections of fluid have been ruled out. By means of exploratory puncture, bacteriologic and microscopic examination of fluid is made possible, throwing much light upon the etiology, prognosis, and treatment. Palpatory puncture, to use Rosenbach's expression, may be of great value in the diagnosis of an underlying tumor, and may be the only means of determining the presence of the thick fibrous plates which sometimes line the chest.

A paper, entitled

THE SIGNIFICANCE OF CERTAIN SIGNS AND SYMPTOMS IN HEART INSUFFICIENCY,

was read by DR. B. W. SIPPY of Chicago, and was followed by one on

THE SMEGMA BACILLUS

by DR. J. L. MILLER of Chicago. The following deductions were drawn: First, over the entire surface of the body and exposed mucous membrane, and especially on the genitals, bacilli are found which resemble morphologically and in tinctorial qualities the bacillus of tuberculosis. Second, from the external genitalia they frequently gain access to the urine, especially in women, and may be a source of error in the examination of urine for tubercle bacilli. Third, the smegma bacillus presents wide variations in size and form, thus rendering morphologic differentiation frequently impossible. Fourth, while most smegma bacilli are more readily decolorized by any of the solutions commonly employed, occasionally they possess equal or even greater resistance than the bacillus of tuberculosis. Fifth, methods of decolorization, where acids alone are employed, are fallacious; acid-alcohol or dilute alcohols, unless long continued, are equally unreliable. Better, but not free from error, is the use of absolute alcohol for at least five minutes. In ammoniacal urine, however, such prolonged use of alcohol may also remove the stain from the tubercle bacillus. Sixth, attempts to remove the fat or fatty acids from the bacilli by ether, chloroform, or other solvents, fail to furnish us with a means of differentiation. Seventh, we must rely on means of excluding the smegma bacillus from the urine. It has never been demonstrated in the bladder, and apparently seldom involves the deep urethra; therefore, by cleansing the external meatus and withdrawing the urine with a catheter we can exclude this possible source of error.

REMARKS ON THE TREATMENT OF NEURASTHENIA was the title of a paper by DR. HUGH T. PATRICK of Chicago. He said that for the production of neurasthenia, as for the production of nearly all disease, two conditions are essential: First, a noxious agent, and, second, a relative vulnerability of the organism or of some part of it. The ratio of these two etiologic factors may be called the etiologic index. In some cases the first effect, that is, the extraneous agent, will be very prominent, the organism itself being considered as normal. In others, the exciting agent will be exceedingly slight, the inherent susceptibility or instability of the patient being an essential causal condition. Each of these two classes of neurasthenia will naturally need radically different treatment. In the first, those in which the patient once possessed of a normal nervous system which has simply been overstrained and overdrained, the important features of treatment are rest and recuperation. In the second class of cases, those in which an unstable nervous system of the individual is at fault, the treatment is essentially mental, and the best way of administering it is by systematic education. For such patients isolation and an initial period of rest may be very useful, but for the further treatment gradually increasing physical exercise and mental occupation are necessary.

DR. GEORGE W. COX of Chicago followed with a paper on

STREPTOCOCCAL INFECTION,

in which he briefly discussed the subjects of puerperal septicemia, erysipelas, phlegmon, diphtheria, scarlatina, and tuberculosis, and reported several cases of streptococcic infection, which he said can be easily detected and cured if the proper means are employed at the proper time. A microscopic examination will confirm the diagnosis and Marmorek's serum will effect a cure.

DR. GEORGE W. JOHNSON of Chicago contributed a paper, entitled

OBSERVATIONS ON THE BLOOD OF TUBERCULAR PATIENTS.

These observations were made on patients in the advanced stage of the disease, with cavities, and, at times, hemoptysis. As to the cause of the apparent anemia in tubercular patients, Cabot and others have discovered that it is not due to a reduction in the hemoglobin. The same authorities state that in uncomplicated tuberculosis the number of red corpuscles remains practically normal. Dr. Johnson paid especial attention to the patient's physical condition as to cavities and hemoptysis. The observations were made before meals, and no attacks of hemoptysis occurred between the first and second examinations. The patients were up and out of doors most of the time during the day. The microscope was used to compute the blood count. Of thirty-three patients examined all had cavities of various sizes, and all had had hemorrhages or hemoptysis. Of these thirty-three patients twenty-five were found to have leucocytosis, that is, the white cells ranged above 7500 per centimeter. These twenty-five also showed cavities. Cabot and others state that there is always a leucocytosis when there are cavities and after hemorrhages. Nine of the thirty-three showed a red-blood count of 5,000,000 or more, which Cabot states as a normal basis. The remaining twenty-four showed a red-cell count in many instances far below 5,000,000, and in no case was the hemoglobin up to normal. In only one case did it reach seventy-five per cent.

Having made observations to determine the character of the blood, he also made some therapeutic observations, using 5-per-cent. nucleinic acid, No. 2, in the first 10 cases; 5-per-cent. nucleinic acid, No. 1, in the second 10 cases; ferratin in 6 cases, and heminol in 5 cases. The first 10 patients were given 22 cubic centimeters every four hours for twenty-four hours. The second blood observation in the first 10 patients showed 6 out of the 10 to have a still greater leucocytosis. The red-blood count was practically unchanged. The hemoglobin showed an increase of from 3 to 10 per cent. in those instances in which there was a leucocytosis. The second 10 were put on the nucleinic solution, No. 1, which was chemically pure and for hypodermic use. Thirty minims were given hypodermically every four hours for twenty-four hours. The second count in these showed the same condition as in the first 10, who were given No. 2 solution by the mouth. None of the patients complained of any bad effects, but experienced a sense of renewed energy, the circulation being better and the appetite improved. He had noticed repeatedly the splendid stimulating effect of nucleinic acid in every case in which he had used it.

Five patients were put upon heminol, 15-grain doses being given every four hours for thirty-six hours. A second examination of the blood of these patients showed an increase of the red cells in four cases. Three showed an increase in the number of white cells, and only two showed an increase in the percentage of hemoglobin. The blood of the thirty-three patients was stained and studied, and in but two cases was there found a poikilocytosis.

CHELIDONIUM MAJUS IN INOPERABLE CARCINOMA, was the title of a paper by DR. C. C. HUNT of Dixon. He had employed this remedy in three cases and concluded that (1) chelidonium majus, injected interstitially into the substance of a carcinomatous growth, tends to its obliteration and necrobiosis. (2) Copious and frequent interstitial injections of the fluid extract are unattended by danger to the patient, if judiciously used. (3) In cancer of the rectum, even at an advanced stage, stenosis may be prevented and the necessity of palliative colotomy obviated. (4) It is a deodorizer. (5) There is some warrant for the belief that it has a favorable influence over glandular infiltration and tends to prevent metastasis. (6) It is hemostatic and antiseptic. (7) It gives the patient hope of ultimate recovery, and this tends to mitigate or annul the awful apprehensions of impending dissolution. (8) More comprehensive and exact experiments are necessary in order to determine the real value of the drug.

The presidential address was delivered by DR. J. M. G. CARTER of Waukegan, who selected for his subject

ADVANCES IN THE DOMAIN OF PREVENTIVE MEDICINE.

The chief object of the address was to show that a responsibility, almost an emergency, exists in the field of preventive medicine, and that this responsibility rests upon the State. He outlined what seemed to him to be a partial possible solution of the problem and presented the following propositions as expressing his ideas of what is necessary: (1) The State or municipality should give men who cannot secure other work some kind of employment which will afford them a living. (2) This may be done by introducing such public improvements as will add to the comfort of the people or otherwise benefit them or enhance the value of property. (3) A minimum rate of wages should be paid so that only those who cannot find work elsewhere will seek such employment. (4) All able-bodied men without work, who have no visible means of support and who do not apply for such government employment, should be subject to draft for this labor. (5) The unfortunate and disabled poor should be cared for as wards of the State. (6) The State should see that the poor are properly or comfortably domiciled in houses provided with good ventilation, supplied with good water, and sufficiently warm. (7) Inspection of the homes of all the people should be conducted regularly and thoroughly, the object being to see that they are in good sanitary condition. (8) All foods put upon the market, as meats, vegetables, fruits, dairy products, milk, and manufactured products should be inspected as to their source, composition, and present condition. (9) Public baths should be established where the poor can have facilities for bathing free, or at a nominal cost. (10) These provisions should be enforced under conditions which will not interfere with the freedom of a liberty-loving people.

DR. J. W. PETTIT of Ottawa then delivered an address, choosing for his subject,

STATE CONTROL IN MEDICINE.

He detailed interestingly the progress of legislation in favor of stricter requirements for the licensing of medical students. The old diploma law in Illinois was instanced. He referred to the movement for the passage of a bill raising the requirements for the practice of medicine. This agitation would eventually lead to the wiping out of sectional lines among medical systems.

In the absence of Dr. Nicholas Senn of Chicago, who was to have delivered the address on surgery, entitled "The Surgical Treatment of Intestinal Tuberculosis." DR. JOHN H. FINLEY, President of Knox College, was introduced and spoke on

INTELLECTUAL BACTERIOLOGY.

He referred humorously to various kinds of germs, such as the micrococcus egotisticus, a germ which impells one to look out for himself and get everything he can. The wool-gathering microbe often afflicts students and brings about in them a revulsion to thoughts of labor. Another microbe is the bacillus bombasticus, and still another the micrococcus oratoricus, found frequently in Knox College. The spirillum Americanus abounds largely in the blood of such men as Admiral Dewey.

SECTION ON ETIOLOGY, STATE MEDICINE AND MEDICAL JURISPRUDENCE.

DR. DANIEL R. BROWER of Chicago in the Chair.

The first paper read in this Section was by DR. GEO. N. KREIDER of Springfield who stated that no law passed by the State Legislature will succeed in driving out the quacks who are practising in this State. He offered some suggestions regarding the position of the Board of Examiners, the fees to be charged, and the penalties to be imposed for violation of the statutes, if passed.

DR. HAROLD N. MOYER of Chicago followed with remarks on

WHAT SHOULD BE THE LAW IN THE STATE OF ILLINOIS?

He said that a new restrictive law is particularly needed because a great number of quacks are practising in the State under the protection of the present State license. He sanctioned the clause in the proposed new bill providing that each licensed physician shall register his name with the State every year.

DR. L. N. RYAN of Galesburg spoke of the advantages of separating the State Board of Health from the Examining and Licensing Board. The duties of the State Board of Health have become so arduous that it can not attend to the additional duties of an examining and licensing board.

DR. J. O. DECOURCY of St. Libory gave a summary of the laws governing expert testimony in other States and countries.

DR. SANGER BROWN of Chicago pointed out the defects of laws governing expert testimony in Illinois, and said that under the present law an expert is usually allowed a fair opportunity to express his views in the case on trial, and, if honest and competent, he need have no fear of cross-examination; but if dishonest and incompetent he is likely to fare badly and to cast discredit upon the profession.

DR. FRANK P. NORBURY of Jacksonville spoke on the same subject, and said there are three essential elements in connection with expert testimony: First, what is the own value of the expert, meaning his ability and honesty? Second, what are the established facts in the case upon which he bases his opinion? Third, what have been his opportunities for examination of these facts? Upon such a basis the courts recognize the value of expert testimony, and, in the general questions of science and skill are disposed to give just weight and consideration to an expert opinion when expressed.

DR. D. W. GRAHAM of Chicago read a paper in which he offered sugestions for outlines of a law regulating expert testimony. He said that in the minds of those desiring legislation on this subject there are two distinct things to be accomplished; one pertains to compensation of the expert witness, and the other looks toward some method of securing impartial testimony of such character as will command the confidence of all concerned.

DR. DENSLOW LEWIS of Chicago related his personal experience with the Dixon decision. He referred to its salient points as well as to the arguments of counsel and

the factors which apparently influenced the Appellate and Supreme Courts in arriving at the decision in this case.

DR. J. A. EGAN of Springfield talked on the subject of legislation necessary to promote better sanitation throughout the State.

The Society voted its unanimous approval of the new Medical Practice Bill to be presented at the next meeting of the State Legislature.

SECTION ON SURGERY, SURGICAL SPECIALTIES, AND OBSTETRICS.

DR. J. L. WIGGINS of East St. Louis in the Chair.

DR. HENRY F. LEWIS of Chicago read a paper on

UREMIA IN THE PROCESS OF CHILD-BEARING.

Uremia was defined as a condition of the system resulting from the retention in the blood of toxic products which should normally be eliminated chiefly in the urine. Eclampsia is a frequent sequel of uremic phenomena occurring in the course of the child-bearing process. The author in discussing the subject included the eclampsias, neuroses, psychoses, and other symptoms due to the toxemia accompanying or following pregnancy. He also included the albuminuria of pregnancy.

DR. FRANKLIN H. MARTIN of Chicago followed with a paper on

THE OPERATIVE TREATMENT OF CARCINOMA UTERI.

The following is a summary of the paper: (1) A microscopic examination of the tissue of the three portions of the uterus should be made whenever one of the well-known classical symptoms of carcinoma appears. (2) Carcinoma of the vaginal portion of the cervix should be treated by vaginal hysterectomy, including the upper portion of the vagina and as much of the base of the broad ligament as it is possible to include, with the ureters pushed well to the side of the pelvis. (3) Carcinoma of the body of the cervix should be treated by vagino-abdominal hysterectomy, with thorough removal of the broad ligament and the deep iliac glands. (4) Carcinoma of the body of the uterus should be treated by thorough removal of the uterus by vagina or abdomen so as to include the tubes and ovaries. The iliac glands should be removed if involved. (5) Neglected carcinoma should never be abandoned, but should be symptomatically relieved by curettement and cauterization, if the more radical procedure no longer seems practicable, with the possible hope of permanent relief in a small percentage of cases.

CONSERVATION OF TISSUE AND FUNCTION IN PELVIC SURGERY.

The author of this contribution was DR. HENRY P. NEWMAN of Chicago. The object of the paper was to stimulate investigation along the line of greater conservatism of the genital health of women. This may be aided (1) by a deeper study of the problems of cell nutrition and general metabolism, in order to determine the relative value of glandular and other structures, and the relation of the pelvic organs to the great systemic laws. (2) By seeking the habits of regimen of individual patients as to diet, dress, social and educational life, etc., for the causes of disease, remembering that these, if allowed to go uncorrected, may handicap the best efforts of medical science and effectually undo all that may be accomplished. (3) By giving to every definitely diseased structure the best opportunity to recover its function that science can devise, by prophylactic supervision of life and habits, by palliative treatment when it offers relief, and by prompt resort to surgical interference when it is called for in the interests of true conservatism.

DR. WELLER VAN HOOK of Chicago described a new device for facilitating operations about the anus. Starting from the proposition that existing technical methods fail to provide means of aseptic or even approximately aseptic operating, especially in view of Cohn's demonstration of the penetrability of fresh cautery-eschars by pathogenic micro-organisms, he reasoned that we should seek means of operating upon hemorrhoids and other anal lesions by dissection and suture. The device consists of a one-half inch rubber drainage-tube perforated near one end and drawn through a minute opening in a piece of medium-weight dentists' rubber dam tissue twelve inches square. It is essential to success that the bowels be prepared beforehand. The method recommended is (1) laxatives to thoroughly evacuate the bowels, on one occasion only, four or five days before the operation. (2) Daily colonic flushings thereafter. (3) After the laxatives have acted, one or two drams of bismuth subnitrate daily in divided doses to keep the colon empty. In operating on hemorrhoids, the following technic is employed: The sphincters are stretched, the rectum irrigated, and the tube with its covering introduced by means of an eight-inch forceps. To keep the umbrella-like device from slipping out, and to keep the dam in contact with the rectal wall, some strips of gauze are pushed up into it, between the tube and the dam. The dam is then pushed aside, the tissues washed again with antiseptics and the hemorrhoids excised and the wound sutured. A piece of iodoform gauze saturated with compound tincture of benzoin is then inserted between the dam and the anal wall. The apparatus and dressing are left undisturbed for four or five days.

A paper, entitled

THE TREATMENT OF ACUTE ABSCESS AND GANGRENE OF THE LUNG,

was read by DR. A. E. HALSTEAD of Chicago. He said that it is only within the last few years that well-known surgical principles have been applied to intrathoracic suppurative conditions. The term abscess of the lung was employed in the paper to designate only acute suppurative inflammation, non-gangrenous, which has its seat within the lung tissue; therefore, cavities filled with pus, formed either by a dilated bronchial tube or by destruction of lung tissue from tubercular infection, were not considered. The causes of acute abscess of the lung were dwelt upon, the principal one being lobar pneumonia. The surgical treatment of lung abscess comprehended puncture of the abscess, aspiration, incision of the lung, and drainage. The author dwelt at length upon the

technic of pneumotomy for abscess or gangrene of the lung.

DR. JACOB FRANK of Chicago read an instructive paper, entitled

PATHOLOGICAL HISTOLOGY OF INTESTINAL UNION AFTER THE USE OF THE FRANK BONE-COUPLER.

From a microscopic study of the healing of intestinal wounds after the use of various suture methods and mechanical devices, he had arrived at the following conclusions: (1) That no suture method insures an exact coaptation of the various layers. The Czerny-Lembert suture, considered one of the best of the many suture methods, does not insure a perfect line of apposition. In a specimen three weeks after operation, in which this suture had been used, there was a marked turning-in of the ends of the bowel. The mucosa in the specimen had not yet regenerated. (2) In regard to the invagination-suture method, he referred briefly to but one, namely, that of Harris, which he said would stand as a type for others. Union takes place, but the different layers are not in juxtaposition, and the lumen of the bowel is greatly encroached upon. (3) That all suture methods leave the subsequent lumen of the bowel more stenosed than either the Murphy button or the author's coupler.

A PLEA FOR EARLY OPERATION FOR LACERATIONS OF THE CERVIX UTERI.

DR. JOSEPH B. BACON of Chicago read a paper on this subject. After referring to the Emmet and Schrader operations for the repair of the cervix, Dr. Bacon described a new adaptation of pathologic facts, as recognized in the disease affecting non-striped muscles and fibrous tissues in other organs, and showed how like conditions may help to cause some of the serious results found in neglected cases of severe lacerations of the cervix. He claimed that the destructive changes found in both the fibrous and muscular tissue of the cervix, and later in the body of the uterus, are due to the persistent chronic inflammation, and that these changes can be avoided by an early operation, but if neglected, there is no limit to the destruction, and in time no operative procedure will more than relieve a part of the symptoms, and cannot remove the diseased tissue and cure the woman. He claimed that the same pathologic laws that explain cicatricial strictures of the rectum, as advocated by Harrison Cripps, apply equally well to the cicatricial changes that are found in the cervix uteri, because there is a like anatomic make-up of the muscles, glands, and excessive fibrous tissue normally present in both. First. the tendency of fibrous tissue, subjected to chronic inflammation, to become both hypertrophied and contracted, and second, the tendency of muscular fibers, when subjected to undue and persistent nerve irritation, to undergo fibroid degeneration with permanent atrophic contraction of its fibrous elements.

The following officers were elected for the ensuing year: President, T. J. Pitner of Jacksonville; first vice-president, Harold N. Moyer of Chicago; second vice-president, J. T. McAnally of Carbondale; permanent secretary, Edmund W. Weis of Ottawa; assistant secretary, W. F. Grinstead of Cairo; treasurer, George N. Kreider of Springfield. Place of meeting, Cairo; time, third Tuesday in May, 1899.

REVIEWS.

A SYSTEM OF MEDICINE BY MANY WRITERS. Edited by THOMAS CLIFFORD ALLBUTT, M.A., M.D., LL.D., Regius Professor of Physics in the University of Cambridge. Vol. V. New York: The Macmillan Co.

THIS volume begins with the discussion of the diseases of the liver, including under this category Weil's disease. Particularly excellent is the chapter on jaundice which, though founded on Frerich's old classification seemingly, is much more modern and inclusive. The attacks of gallstone colic without the presence of icterus are clearly presented and the other diseases of the hepatic organ are considered in full. We scarcely can commend the addition of icterus neonatorum to diseases of the liver, but perhaps this condition is as well considered here as under any other caption. The pancreatic diseases are next taken up by Dr. Reginald H. Fitz, the only American contributor to the volume except Dr. Henri A. Lefleur of Montreal, who has contributed an article on "Amebic Abscess of the Liver."

The diseases of the kidneys are next described, beginning with general pathological considerations of the renal functions. Nephroptosis, in which the distinction between floating and movable kidney is strictly defined, and the albuminuric renal diseases follow. The surgical diseases of the kidney are next considered, together with an admirable little chapter on the differential diagnosis of renal tumors.

One will read the chapters on the diseases of the lymphatic and ductless glands with especial interest, not only because of its inherent excellence, but because its authors' names are familiar in this domain of medicine—Drs. Ord, Mackenzie, Rolleston, and Murray. Scrofula is discussed by Professor Allbutt, and its surgical aspect by Mr. Pridgin Teale. We note only that the *habitus lymphaticus* of Paltauf is not mentioned. "Obesity" and its treatment are next taken up in an admirable manner by Sir Dyce Duckworth.

There is nothing better in the whole system than Dr. A. Ransonie's "General Pathology of Respiratory Diseases." It is a treatise in itself and is made so clear that, although this is not a work for students, it would well repay them to read this short monograph. It is well supplemented by Dr. Mackenzie's article on the physical signs of diseases of the lungs and heart. The graphic charts given with it elucidate the text exceptionally clearly. The volume closes with three chapters devoted to the diseases of the nose, the pharynx, and the larynx respectively.

One cannot fail to be impressed in the reading of this volume with the philosophical treatment of the subjects, quite in keeping with the tone of those which have gone before. The conception of this system of medicine is unique and emphasizes in no uncertain way the fact that the modern physician must be a thinking man if he would be a

physician at all. The scientific tone, the logical presentation of facts, the admirable arrangement and, above all, the authority of the various articles is bound to make this system a classic among books of its kind.

APPLIED BACTERIOLOGY. An Introductory Handbook for the Use of Students, Medical Officers of Health, Analysts, and Sanitarians; 464 pages and nine plates. By T. H. PEARMAIN and C. G. MOOR, M.A. Second edition. London: Baillière, Tindall & Cox, 1898.

THIS handbook of bacteriology is a very commendable one. The purpose is to give an account of the principal facts of bacteriology which may have practical application. After a brief history of bacteria and reference to their origin, growth, and destiny, the authors devote about 100 pages to a description of bacteriologic apparatus, methods of bacteriologic study, methods of spread of disease, immunity, and sero-therapy. The discussions of individual organisms include that of tuberculosis, leprosy, anthrax, typhoid, diphtheria, cholera, erysipelas, gonorrhea, glanders, syphilis, influenza tetanus, malignant edema, bubonic plague, pneumonia, relapsing fever, scarlet fever, smallpox and vaccinia, hydrophobia, malaria, actinomycosis, yellow fever, cholera nostras, infantile diarrhea, and the pyogenic organisms. By way of criticism, it may be said that scientists do not admit that the organisms which are attributed as causative of some of these diseases, are so in reality, and it would seem that the authors have not always been as critical as they are warranted in being by fact. For instance, they state positively that the organism causing influenza is that described by Pfeiffer, but such a bold statement does not carry conviction. The writers' inclinations toward the eager acceptance of the claims of bacteriology are further seen in their statements that "Lustgarten's bacillus is probably the specific organism of syphilis; a streptococcus described by Klein in 1882 is probably the cause of scarlet fever."

There are chapters on disinfection and disinfectants, on fermentation, and on the bacteriologic examination of water, milk, filters, etc., and the volume closes with a discussion of the characters of some commonly occurring organisms not fully described in previous pages. The book may be recommended as a fairly accurate reflection of the status of bacteriology at the present time. It will appeal to the general medical reader, to the dilettante in science, and to those engaged in pursuits allied to medicine rather than to the advanced medical student.

A MANUAL OF GENERAL PATHOLOGY FOR STUDENTS AND PRACTITIONERS. By WALTER SYDNEY LAZARUS-BARLOW; 795 pages; $5, net. Philadelphia: P. Blakiston, Son & Co., 1898.

THIS is one of the important books of the year. Not that it contains much that is new, but the writer's point of view is in many instances so individualized and so well presented that old facts are laden with greater suggestiveness. During the past few years a large number of most commendable treatises on pathologic anatomy have appeared, but there has been a dearth of works on general pathology. The vegetable micro-organisms, with especial reference to the bacteria, are discussed before the pathology of the circulation and the blood and the pathology and sequels of inflammation are taken up, while the pathology of infection follows these chapters. This is an arrangement which commends itself to the reader. So much cannot be said for the arrangement and sequence of some of the other chapters. For instance, the pathology of nutrition is sandwiched between the pathology of shock and collapse and the pathology of respiration, when it should follow the chapters on inflammation.

The author's pages give much evidence that he has a comprehensive grasp of the subject, and that he has a logical, temperate mind. The book is one that will be read by the student because its context should be as familiar to him as the truths of physiology, and by the physician because he will find it not only interesting but enlightening. We regret to say that the printing, paper, and binding are all inferior, as is the case with so many of the books printed in Great Britain and sent to this country to be published.

ATLAS AND ESSENTIALS OF PATHOLOGICAL ANATOMY. BY DR. O. BOLLINGER. Vol. 1. Circulatory, Respiratory, and Digestive Apparatus. New York: Wm. Wood & Co. (Wood's Medical Hand Atlases.)

THIS excellent little volume admirably fulfils its purpose. The sixty colored plates are alone worth the price of the book. The text shows many barbarisms of construction and diction which might easily have been obviated by submitting the translation to a competent medical reader. The book is well bound and satisfactorily printed on good paper.

THERAPEUTIC HINTS.

For Renal Colic.—

Morphin hydrochlorat. . . .	gr. iv
Atropin sulphat.	gr. $\frac{1}{10}$
Ag. laurocerasi	ʒ vi.

M. Sig. One teaspoonful as initial dose, cautiously increased or repeated if indicated.

For Phosphorus Poisoning.—

℞ Ol. terebinthin.	ʒ iiss
Syr. aurantii cort.	ʒ iiss
Mucilag. acaciæ	ʒ iii.

M. Sig. To be taken in three portions, each time well shaken.—*Vetter.*

For Coryza.—Gaudin asserts that the most intense coryza can be arrested, especially in the initial stage, by inhalation through the nostrils of the vapor of formic aldehyd in forty-per-cent. solution. This treatment also helps to diminish the fetidity in ozena.

For Acne Vulgaris.—

℞ Sulphur præcipitat. . . .	gr. lxxv
Zinci sulphat.	gr. xlv
Potassii sulphat. } aa . .	ʒ iss
Potassii sulphurat. }

VOL. LXXIII. NEW YORK, SATURDAY, JULY 30, 1898. NO. 5.

ORIGINAL ARTICLES.

HEREDITARY INFANTILE SYPHILIS.[1]

BY J. HENRY FRUITNIGHT, M.D.,
OF NEW YORK;
VISITING PHYSICIAN TO ST. JOHN'S GUILD HOSPITAL.

HOWEVER interesting the various sources of acquired infantile syphilis may be, it is not proposed to consider them here, but only to treat of the hereditary variety. Nor is it intended to cover the whole field, for then the limits of this paper would extend further than the time allotted. Nor is it meant to be implied by the title that the author believes in the existence of tardy or belated hereditary syphilis, for he is inclined to agree with those writers who are of the opinion that in those cases which are designated as *syphilis hereditaria tarda*, the symptoms of the disease probably escaped recognition earlier in life. Strictly speaking, the term hereditary syphilis should only apply to those cases in which the infection occurs at the time of conception. From a clinical standpoint it is more practical to designate all cases, whether the subject is infected at the time of conception or subsequently, as congenital syphilis.

It has been definitely determined that there are three modes of infection: First, the woman being syphilitic, the ovum is infected; second, infection of the ovum through the spermatozoa; and, third, after conception by the intra-uterine transmission of the infection to the fetus. As there is no direct communication between the lymphatics or blood-vessels of the mother and the fetus, the transmission must take place through the layer intervening between the placenta and the decidua. Hence, the infection of the fetus probably depends upon the relative strength of the leucocytes on the fetal and those on the maternal side. If the placenta be healthy, it is possible for the infant to escape the infection even although the mother herself be syphilitic. If infection of the woman does not occur until about the last two months of pregnancy the fetus usually escapes the disease. The first effect of infection upon the woman is sterility, but with the lapse of time its virulence may abate; pregnancy will occur which is usually interrupted before the seventh month. The disease may be inherited from either one or from both of the parents. If both are syphilitic the child is usually syphilitic, although it need not necessarily be so. Nor is the disease more severe in the child if both parents are syphilitic than if one parent only be affected. The stage of the disease in the person of the progenitor will determine the transmissibility of the infection to the offspring, for if both parents are suffering from secondary symptoms transmission will be almost certain. If active treatment shall have been carried on for several months and the child be born when no active symptoms are present in the parents, or if the symptoms are tertiary in character in the parents, the child will probably escape. The first-born is more likely to suffer more severely from the infection than later born children, provided infection of the parents has occurred previous to the birth of all the children.

Quite recently in the *Wiener Klinische Wochenschrift* for 1897, vol. x, p. 564, Dr. K. Hochsinger has advanced a new theory of the development of congenital syphilis. He maintains that in the fetus and in young infants, in its early manifestations, congenital syphilis is characterized by a tendency to diffuse infiltration, whereas in the early forms of acquired syphilis the type of a circumscribed cell proliferation is observed. He also claims that another peculiarity of congenital syphilis consists in the existence of diffuse changes in the integument analogous to those found in the viscera of the fetus. In support of the theory it is pointed out that the diffuse syphilitic inflammatory processes always first attack the large intestinal glandular organs of the fetus. There is no syphilitic fetus and no syphilitic stillbirth in which the liver is not the seat of a diffuse vascular and interstitial disease, and in two-thirds of all such cases the kidneys, pancreas, and lungs are unquestionably similarly affected. Hence, the logical conclusion is, according to Hochsinger, that the virus of hereditary syphilis must possess a predilection for the parenchyma of the glands, otherwise it would be impossible to explain the fact that syphilitic fetuses are attacked by a diffuse inflammation of the intestinal glands, while all the tissues of the organism escape such syphilitic affections during the early months of fetal life. The history of the development of the fetus will explain this, for during fetal development the syphilitic virus finds in these organs, which have a generous blood and lymph-supply, the most favorable places for its activity. In those parts of the organism in which the

[1] Read before the Northwestern Medical and Surgical Society of New York, May 18, 1898.

circulation is less free, as in the long bones of the fetus, the syphilitic lesions first develop at the point of largest blood-supply, and not at all in the adjacent structures. Hence, it is wrong to regard the visceral affections of the fetus and infant as tertiary in character. They should rather be looked upon as the first indications of congenital syphilis, and resemble those changes which may be demonstrated in the diffuse syphilitic inflammatory conditions of the skin in the infant. The natural history of fetal development likewise explains the frequent death *in utero* of the children of syphilitic parents.

The lesions in hereditary syphilis are more uniformly present in the bones than elsewhere. The long bones are chiefly involved, and usually at the junction of the shaft with the epiphysis. Of the viscera, the liver is probably more often the seat of syphilitic lesion in the fetus and the newly born child than any other organ. There may be an interstitial or a gummatous hepatitis, or a combination of the two. The intestinal canal very rarely shows any lesion. Catarrhal rhinitis and pharyngitis are almost constant symptoms of early cases. Fissures at the anus are frequent, extending occasionally into the rectum. At the time of birth symptoms are present in a very small number of cases, and then the infection is extremely severe and the child lives but a few days. The general appearance of these patients is miserable in the extreme. The body is greatly emaciated, the skin is wrinkled, and has lost its elasticity, the temperature is apt to be subnormal, and the spleen and liver are usually enlarged. They suck feebly or not at all, and, if untreated, die very soon.

The more intense the infection the earlier the symptoms will appear. They are usually observed between the second and sixth week, although the period is variable. Some observers have stated that several years may elapse before the appearance of symptoms, but very good authorities hold that if they do not appear within one year after birth the child may be considered free from the infection. Three-fourths of the subjects develop symptoms within the first three months. Generally the first symptom is the coryza, commonly called "snuffles," which is very persistent. Sometimes the constitutional symptoms precede the local ones, but usually the reverse obtains. At times a hoarse cry may accompany the coryza without the larynx participating in the catarrhal condition. Tenderness may exist about the joints, due to epiphysitis. Soon after the coryza eruptions will appear, first on the palms of the hands and soles of the feet and then on the face. Fissures will appear at the angles of the lips, and mucous patches will be seen on the lips and inner surface of the cheeks. The latter may also be seen at the verge and just within the anus. The eruption is usually macular, small, and dark-red in color. It is sometimes circular, and often a little elevated. It is not accompanied by any surrounding inflammation nor by itching. It gradually becomes coppery in hue, and requires from one to three weeks for development. It lasts for a period varying from three to eight weeks. Of course, if active treatment be employed, the period of its existence is shortened. Papular and squamous eruptions may also at times be present. The mucous patches and the fissures are among the most characteristic features of hereditary infantile syphilis. Radiating scars at the angle of the mouth are, therefore, invariable diagnostic features of the disease. These fissures are deep, bleed easily, and are very obstinate to treatment. Lymph-nodes are infrequently or seldom present. That condition of the teeth known as "Hutchinson's teeth" cannot be considered as pathognomonic of hereditary syphilis.

The prognosis in hereditary infantile syphilis is generally worse than in acquired infantile syphilis. This is true not only as regards life, but also as to the determination of the future constitution of the subject. It is also very difficult to reduce to a minimum the remote baneful influences of the infection. The later the disease manifests itself after birth the better will be the prognosis. In the hereditary variety relapses are not so apt to occur as in the acquired cases.

If it be permissible to perpetrate an Irish bull, the treatment of a syphilitic infant should begin before there is an infant. That is, if a syphilitic woman becomes pregnant she should at once be placed upon specific treatment, and thus probably secure the escape of the fetus from the threatened infection. In my own experience I can recall two particularly remarkable cases of this character. A syphilitic woman had aborted seven successive times, varying from the third to the seventh month of pregnancy, as a result of her infection. She consulted me at about the first month of her eighth pregnancy. I at once placed her upon specific treatment, with the addition of tincture of iron and chlorate of potash, as used by the late Professor Fordyce Barker, and at the termination of the ninth month delivered her of a large, healthy boy, who has never developed any indication of the disease. The other case was that of a woman similarly affected who had suffered from four successive abortions due to syphilitic infection. The same course was pursued as to treatment, with equally gratifying results as in the first case.

There is among physicians a disposition to stop treatment of a pregnant syphilitic woman toward the

last months of gestation. This is an error. Treatment should be pushed vigorously up to the very last moment. When it is known that either one or both parents are syphilitic, procreation should be forbidden for a period of at least two years, during which active treatment should be instituted. Then, after six months shall have elapsed without treatment and with no manifestations of the disease, procreation may be permitted.

When there is a reasonable suspicion of the disease in an infant treatment should be begun immediately after birth and vigorously continued. The old indirect method of treatment through the mother's milk is futile, and is deservedly no longer in use. The remedy *par excellence* is mercury. In young infants the best method of treatment is that by inunction. The place of inunction should be changed from day to day. A convenient way of using this method is to place a piece of the ointment on the belly-band, and by the movements of the child and the ensuing friction it is easily rubbed into the skin. The officinal blue ointment is used in this way, but it must be diluted according to the age of the infant. Or the gray powder or the bichlorid of mercury may be given internally. The former in doses of 1 grain four times daily; the latter in doses of $\frac{1}{60}$ of a grain four times daily, well diluted. If the symptoms be urgent, or if it be desired to bring the system more rapidly under the influence of the mercury, calomel should be given in doses of $\frac{1}{10}$ of a grain four times daily. The treatment with mercury should be continued for at least one year. During the last half of the year the amount per day can be reduced by one-half or by one-third. If the mercurial treatment be persisted in for a longer period than one year it will be advisable to interrupt its administration occasionally. Some have expressed a fear of administering mercury to children for so long a period, claiming that it would produce dysentery, salivation, and other disagreeable complications. This fear, I think, is not well grounded, for children tolerate mercury extremely well, and very much better than adults. Salivation is very rare indeed. The symptom which would indicate that the child is becoming profoundly affected by the drug is the occurrence of pronounced anemia. I myself give to children from half a year to two years of age in the treatment of diphtheria the bichlorid of mercury in doses of $\frac{1}{48}$ to $\frac{1}{32}$ of a grain every two hours, kept up for three and four and even five days at a time, and have yet to see any dangerous symptoms or conditions arise from the administration of these doses. If the symptoms resemble those of the tertiary stage in the adult the iodid of potassium may be given, from 20 grains to 2 drams *per diem*, according to the age of the child and the severity of the case, and, of course, largely diluted.

In conjunction with the specific treatment, the tonic treatment is of great importance, not only as regards the syphilitic infection, but with the object of getting the constitution of the patient in the best possible condition. Among the remedies to be employed cod-liver oil, iron, arsenic, and nux vomica hold a prominent place.

The local lesions of hereditary infantile syphilis will naturally demand the same treatment which is given such lesions in the acquired variety of the disease, whether in the adult or infant, the strength of the remedies employed always being adapted to the age of the patient.

THE TREATMENT OF FRACTURE OF THE PATELLA BY IMMEDIATE SUTURE.

BY WILLIS G. MACDONALD, M.D.,
OF ALBANY, N. Y.

SUCH a diversity of opinion apparently exists among surgeons concerning the best method of treatment for simple fractures of the patella that I feel constrained to report my recent personal experience, confined to a limited number of cases treated by immediate operative interference. After a considerable experience with various forms of dressings, with fair, indifferent, and positively bad results, and a few cases of suture by the open method, I abandoned them all for the method to be subsequently described. No claim for originality in the various steps of the operation is raised. A number of surgeons have employed the plan in part or with distinctive modifications. The technic carefully followed has yielded uniformly favorable results.

Fractures of the patella having their origin in muscular action are usually transverse, the line of fracture being below the isthmus of the bone. Fully eighty per cent. of them are of this character. Fractures due to direct violence are usually stellate, or distinctly oblique. The encircling suture may not be applicable to all fractures of the second variety, that is, fractures due to direct violence. More or less effusion of blood into the joint is a part of every patellar fracture. The effusion always aids in the displacement of the fragments, and unless removed prevents close apposition of the fractured surfaces.

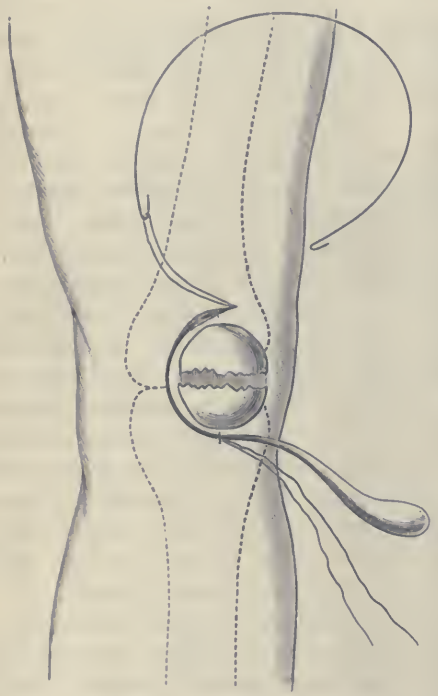
Operation.—As soon as the patient is received at the hospital or place of dressing the limb is thoroughly prepared by scrubbing, shaving, etc., following the usual plan of the surgeon for the sterilization of the skin. Either general or local anesthesia may be employed. I have used Schleich's solution of cocain and morphin in normal salt solution with satisfaction, although local anesthesia doubtless increases

the dangers of infection. However, no accident has followed.

The instruments and appliances required are few: A broad scalpel, two artery forceps, a set of mounted needles (Pean's full curved, three sizes), scissors, a fine needle and catgut, a bobbin of strong silk, a yard of heavy silver wire (sixteen or eighteen gage), a metal cannula of medium size, sterilized gauze, aristol, bandages, and plaster of Paris.

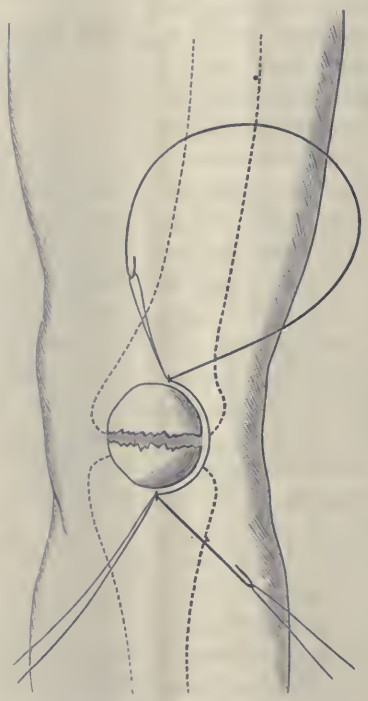
After the usual preparations to secure asepsis have been completed, the limb is fully extended, the surgeon draws the lower fragment of the patella as high as possible, enters the point of the scalpel close to the apex of the bone, and carries it directly inward and upward through the ligamentum patellæ into the synovial sac above the ligamentum mucosum. The scalpel is now withdrawn, leaving a puncture of the joint at its dependent part one-half of an inch in length. This puncture is now covered with sterilized absorbent gauze, and by massage and flexion the joint is practically emptied of effusion through the puncture. Should any difficulty be experienced in removing the effusion, always fluid for several hours after the injury, the metal cannula may be introduced to facilitate its flow. After the removal of the fluid the fragments can usually be brought in apposition. By a little coaxing, bits of membrane or bursa can be removed from between the fragments, and distinct bone crepitus obtained. An assistant now holds the fragments. The surgeon selects a mounted needle, the curve of which is appropriate to the size of the patella, threads it with a loop of strong silk, and passes it in the manner shown in Figure 1. The point of the needle is introduced into the puncture close to the apex of the patella, carried through its tendon laterally, through the aponeurosis at the side into the tendon of the extensor femoris, keeping close to the patella all the time, and is made to present underneath the skin. A touch with the scalpel permits the point of the needle to be reached, and the loop of silk withdrawn. The needle is then removed, and another loop passed in a similar manner on the opposite side. By means of these two loops of silk the silver wire is drawn into postion. (Fig. 2.) The relation of the fragments is now re-examined to determine the absence of tissues between them, and that no tilting exists. When properly adjusted they are steadied by an assistant, while the surgeon, by strong traction on the silver wire, using forceps on each end, buries it in the tissues around the patella and twists it close to the apex. The wire is cut short and buried in the wound. (Fig. 3.) If the process has been carefully followed the fragments will be found in absolute approximation, surrounded and supported by this suture or subcutaneous splint.

Fig. 1.



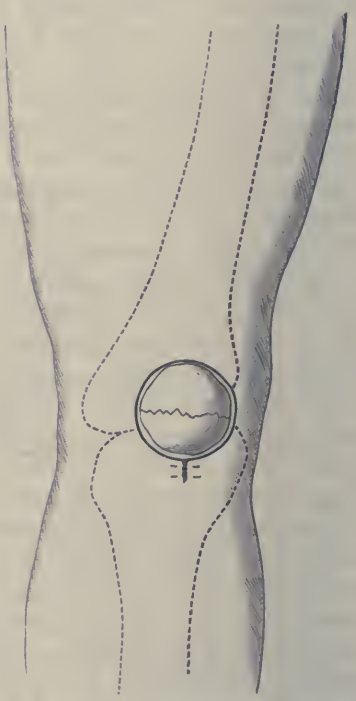
Showing method of passing needle with silk loop.

Fig. 2.



Silk loops in position as carriers for silver wire (shown partly drawn into position).

Fig. 3.



Silver wire in position and buried in the tissues. Punctures closed by catgut sutures.

The punctures are now closed by fine catgut sutures, dusted lightly with aristol, covered with plain sterilized gauze, and the whole limb enclosed in a plaster-of-Paris dressing. The patient is kept in bed with the foot elevated for a week, and carefully watched for any reaction. Afterward he is allowed to sit up, and after two weeks go about on crutches.

FIG. 4.

Pean needle of proper curve (one-half size).

The dressing is removed at the end of six weeks, and a molded posterior splint adjusted. At the end of twelve weeks all dressings are removed and full use of the limb allowed.

Results.—During the last three years in which I have employed this method exclusively for the immediate treatment of patellar fractures, in all seventeen patients were treated, the majority in the Albany Hospital. Eleven were transverse fractures, 2 stellate, and 4 were cases in which the patella had been sawn through in partial resections or erasures

FIG. 5.

Skiagraph showing a lateral view of the knee-joint after transverse fracture of the patella, treated by encircling suture.

of the knee-joint. No single case of infection followed the operation. The heavy silver wire sutures have never required subsequent removal or have interfered with the function of the joint. Complete or useful restoration of function has occurred in every case of simple fracture, and all of the patients (trainmen, stokers, etc.) have returned to their previous occupations. Two patients were trainmen, a trying occupation for bad limbs. In one case the patient, a heavy woman, some six months subsequent to her first fracture, was thrown from a step-ladder and the patella rebroken. The second time the joint was opened by a free incision and the broken wire removed. In examining the fragments bony union was apparent. Dr. Albert Vander Veer, who assisted at the second operation, was satisfied on that point as well as myself. The patients were operated upon usually immediately after the injury, although in two instances the operation was delayed until the fourth and fifth day. The ages of the patients ranged from twenty-three to sixty-five years. Several of them were very stout, especially the women.

The accompanying skiagraph was taken eight months subsequent to the injury by Dr. William Hailes, Jr. The apposition is satisfactory, bony union is apparent, and there is no loss of function in the knee-joint. This view represents some distortion of the position of the silver wire, which is apparent rather than real. Another skiagraph taken of the same knee at the same time shows the position of the wire suture the same as the drawings used to illustrate the technic of the operation.

The advantages of the method may be said to be:

1. Uniformly good results.
2. Shortened period of convalescence.
3. Freedom from the dangers of sepsis if ordinary skill is employed.
4. Simplicity in the technic.
5. The encysted silver wire suture continues after all dressings are removed to act in maintaining the position of the fragments, and in preventing stretching in fibrous or defective union.
6. Bony union is made possible in all, and does occur in many cases.

A STUDY OF THE RECENT EPIDEMIC OF TYPHOID FEVER AT ST. CHARLES, MISSOURI.[1]

BY H. H. VINKE, M.D.,
OF ST. CHARLES, MISSOURI.

THE following is a brief report of an epidemic of typhoid fever which occurred at St. Charles, Mo., during the past fall and winter. There were upward of 200 cases in a population of 7000, but I have been able to obtain accurate reports of only 161 cases. A few physicians ignored requests for

[1] Read before the Missouri State Medical Society.

reports of their cases, some claiming that such reports are useless, while others seemed to look upon investigations of this nature as impertinent inquiries into their business affairs.

I do not think that in any of these cases the Widal test was made use of to confirm the diagnosis, but the characteristic typhoid symptoms were present in all, and they were observed by experienced physicians. It is undoubtedly true that at the time of an epidemic of this character there is a tendency to look with suspicion upon all continued fevers, and typhoid fever no doubt is at times diagnosticated when really some other disease exists; on the other hand, however, at such a time many atypical forms occur and many irregular cases of this affection are not recognized as enteric fever, simply because they do not follow accurately the course laid down in text-books.

Of these 161 cases, 149 patients recovered and 14 died, a mortality of about 8.7 per cent. Two cases occurred in July, 6 in August, 7 in September, 10 in October, 14 in November, 48 in December, 60 in January, and 14 in February. Eighty-seven cases occurred in males and 74 in females. I have records of 11 cases in children under five years of age, 29 cases between 5 and 10 years, 66 between 10 and 20 years, 27 between 20 and 30 years, 4 between 40 and 50 years, 2 between 50 and 60 years, 1 case between 60 and 70 years, and 1 between 70 and 80 years. The youngest person was 2 years of age, the oldest 75.

Complications and accidents arising in the case of those patients who succumbed were of the following nature: Intestinal hemorrhage in five cases, in patients aged 18, 20, 22, 31, and 33 years, respectively, death occurring on the 14th, 19th, 20th, 23rd, and 28th day of illness. Intestinal perforation and peritonitis proved fatal in 4 cases in patients aged 8, 18, 49, and 35 years, respectively. The patient aged 8 years was a little girl who died rather suddenly of intestinal perforation four weeks after the subsidence of the fever; the other three patients died on the 25th, 21st, and 25th day of illness. Pneumonia was a fatal complication in two cases, in patients aged 18 and 35 years, the first patient dying on the 11th day of illness, the second on the 20th day. Meningitis was a fatal complication in one case, in a patient aged 14 years, who died on the 28th day of illness. Active delirium, ending in coma and death, set in in one case, a patient aged 23 years, who for three weeks had an extremely light attack of typhoid fever. This patient died on the 31st day. One patient, aged 18 years, succumbed to erysipelas, while recovering from a very severe attack of typhoid fever. One patient, an epileptic, aged 14 years, died on the 24th day of illness, of exhaustion. The youngest patient who died was 8 years of age, the oldest 49 years.

Complications and accidents in those who recovered were of the following nature: Intestinal hemorrhage in 9 cases, the patients aged respectively 2, 6, 6, 4, 14, 19, 30, 33, and 35 years. Intestinal hemorrhage was by no means always a fatal or even grave accident; in a few instances it brought the fever to a rather abrupt close, which led to an early and complete recovery. Orchitis was observed in one case, in a patient aged 32 years. Lymphangitis of the left leg was met with once, in a patient aged 26 years, nephritis in a patient aged 42 years, and abscess of the lung in a patient aged 10 years. Peritonitis set in in one case on the 20th day of illness. It was probably not the result of perforation, but in all probability was set up by micro-organisms wandering through the coats of the intestines. Abortion at the 6th month of pregnancy was a complication in one case. The mother made a perfect, though somewhat slow, recovery; the child died 24 hours after birth. The temperature at the time of labor was 102.5° F., and six hours later, 104.5° F. In the patient 75 years of age, the oldest that came under observation, an abscess of the left cornea, resulting in the total disorganization of that eye, considerably delayed recovery; large bed-sores in this case still further tended to render recovery very slow.

Recrudescence was of not infrequent occurrence, but I have a record of only one case of true relapse. It would seem to be difficult to explain why true relapse after typhoid fever ever occurs, for if one attack of this fever lends protection and immunity against subsequent attacks, the occurrence of a second attack immediately after the subsidence of the primary attack should not be possible; and if relapses are really of frequent occurrence they would constitute a powerful argument against the usefulness of serum-therapy. Bronchitis was a frequent complication but did not prove fatal in any case. More or less profuse sweats were observed during the entire course of the fever, in many cases, and sudamina at times covering the entire body were noticed during convalescence in these cases. In many instances the prodromic state was altogether absent, the invasion being sudden and abrupt, and the fever high from the beginning. At times obstinate constipation was very troublesome, and in some of these patients I found an unusually slow pulse.

In most instances the patients were treated by the expectant-symptomatic method. Patients were sponged freely whenever the temperature rose above

103° F., and grave symptoms and accidents were treated as they arose. The result of this particular form of treatment has been satisfactory, for the death-rate was but 8.7 per cent. In four cases, however, Yeo's method (chlorin water with tonic doses of quinin) was used exclusively; of these four, two patients died, one recovered after a tedious illness lasting five weeks, and one made a rapid recovery. Three patients were treated exclusively by the antiseptic or Woodbridge method. I will premise my remarks on the result of this particular treatment by the statement that the number of cases in which it was employed was altogether too small to permit me to deduce any conclusions therefrom, and then, too, I am not quite certain as to whether the ideal Woodbridge treatment was brought into use. Tablets containing podophyllin $\frac{1}{100}$ of a grain, calomel $\frac{1}{16}$ of a grain, guaiacol carbonate $\frac{1}{4}$ of a grain, menthol $\frac{1}{16}$ of a grain, thyol $\frac{1}{16}$ of a grain, and eucalyptol were administered every half hour during the first 24 hours, except when the patient was asleep; after this they were given one every hour during the next two days, and one every 2 hours thereafter.

One of the patients had fever 41 days, one patient recovered after 28 days of illness, and one after 24 days. Such a result certainly does not entitle this form of treatment to the name of abortive. The *rationale* of this antiseptic treatment would seem to be difficult of explanation, for even if the intestinal canal could be rendered thoroughly aseptic or antiseptic, it would be difficult to explain how these antiseptics could reach the blood and the liver, and other distant organs in sufficient strength to kill the bacillus typhosus and the toxins thereof. These micro-organisms, as is well known, are not only found in the intestinal canal, but have been discovered in nearly all the organs of the body, and it does not seem to be settled which particular part of the economy is primarily attacked by them.

There is no reason to doubt that the bath treatment, or the so-called Brand method, offers the best chances for recovery, and is attended by the lowest mortality. It is extremely difficult, however, to overcome the prejudice against the cold bath; then, too, a lack of intelligent nurses in the country will probably render the use of the method impracticable except in rare cases; but there is every reason to believe that the closer we come to the rigid Brand method, the better will be the results. The frequent use of water for washing out and cleaning the mouth, the free administration of water, the frequent thorough and prolonged sponging of the patient whenever the temperature rises above 102.5° F.—in a word, hydrotherapy, in the broadest interpretation of that term, together with careful and intelligent nursing, would seem to constitute the best and safest routine treatment in private practice.

It seems to be pretty well settled that the bacillus typhosus is the sole and positive cause of enteric fever, and that it is transmitted by means of the water ingested, or by foods and drinks mixed with infected water. A realization of these facts caused me to make a careful inquiry into the water used by those attacked by the fever. It must be added that at the very outset of our investigations I looked for some common source of infection. Infected cisterns and wells might readily give rise to sporadic cases of enteric fever but could scarcely explain the occurrence of an epidemic of this disease. No cases of typhoid fever occurred in the immediately surrounding country. I therefore had to look for a common source of infection within the city limits. This inquiry disclosed the fact that 130 of the patients drank hydrant water exclusively or occasionally, either at home or at their places of employment, and 31 drank cistern or well water exclusively, at any rate I have no proof that they ever drank hydrant water, but it is possible that quite a number of these drank hydrant water without recalling the fact.

Our water-works are situated in the very heart of the city and the water is obtained from the Missouri River. We have not a perfect system of sewerage, and sewers have in several instances been built in the most prominent thoroughfares. These sewers carry the sewage directly into the river. In March, 1897, a sewer was built on Clay Street, having connections with St. Joseph's Hospital and several residences in this street. Clay Street is about four blocks above the "intake" of our water-works and empties its contents into the river. The first case of which I have any record occurred on the 6th of July, in a house on Clay Street having connections with the sewer above referred to. I secured records of the stage of the water in the Missouri River at St. Charles from the Missouri River Commission, and these records show that in the fall and winter of 1897 the river was lower than it had been for 15 years. During these months the refuse from the Gas Works (which are located about a block above the water-works) could be detected in the hydrant water by a distinct coal-tar taste and odor, and this circumstance still further confirms the well-known fact that whenever the river is low and the current slow and sluggish, self-purification is slow and imperfect. Here, then, we have a record of an unusually low stage of the river, and a positive history of contamination with the excreta of the first typhoid-fever patient of which we have any report. When we add to this the fact that at least 130 out of 161 patients drank hydrant water, either exclusively or occasionally, the

conclusion that in all probability the hydrant water was responsible for the epidemic would seem to be justifiable. The epidemic began to subside as soon as local rains materially increased the volume of water in the river and after the people had been instructed to drink water only after it had been boiled. I will add here that specimens of water for bacteriologic examination were sent to the Secretary of the State Board of Health from a suspected cistern, a well, and from the river after it had risen. No typhoid bacilli were found and the river water contained less organic matter than the two other specimens. Bacteriologists know how very difficult and tedious these examinations of water are, and that painstaking and careful labor of several months' duration often fails to reveal the bacillus typhosus in water that is known to be infected. Failure to find these bacilli does not prove, therefore, that they are absent.

If it be true that the bacillus of Eberth is the sole cause of typhoid fever, and if it be true that this bacillus reaches the human economy almost exclusively through infected water, the inference that a pure and healthy water-supply would render the occurrence of typhoid fever impossible is inevitable. The question of the greatest importance in connection with the subject is, How can we best secure for the individual, the family, and the community a healthful water-supply? If every individual would drink water only after it has been boiled the occurrence of typhoid fever would indeed be rare. Boiling the water, however, will probably only be rigidly carried out at the time of an epidemic. Dr. Bashore, in a most excellent article on "The Prevention of Typhoid Fever in Rural Districts," which appeared in the *Medical Record* of January 15, 1898, points out how a pure water-supply may be obtained in these localities. The people should be taught that cistern-water is the safest and most wholesome for drinking purposes. Wells are constantly liable to contamination because they admit of the entrance of ground-water, and it has been shown that the bacillus of Eberth retains its vitality for an indefinite period in the soil. The walls of the cistern should be of hard-burned brick laid in a first-class cement in such a manner that they are absolutely water-tight. The cistern should have a capacity of about ten gallons a day for each member of the family for two months. By a properly arranged cut-off the first rain-water should be permitted to escape. The walls of privy-vaults should be constructed like those of the cisterns, and the vaults should be frequently cleaned and disinfected. The construction of these cisterns and privy-vaults should be under the direction of the proper county or city authorities. In large cities the water-works should be under the absolute control of the municipal government. Corporations cannot be relied upon to take immediate steps to improve and correct the water-supply when it has become polluted if such changes and improvements entail the outlay of considerable money. The intake of these water-works should be far beyond a point where contamination by sewage is possible, or, where this is impracticable, the use of effective filtering apparatuses should be made compulsory.

WAR ARTICLES.

NEWS OF THE WEEK.

AUTHENTIC reports as to the health conditions of our men in Cuba are scarce, but from all we can gather there is as yet no reason for apprehension. The cases of yellow fever which have appeared in the army near Santiago have been comparatively few and the disease is of a mild type. Very few deaths have occurred and the vigilance and effectiveness of the medical corps is worthy of warm commendation.

. . . . . .

Santiago is a very hot-bed of yellow fever and the Government has wisely decided that the force necessary to occupy it shall be made up of immunes from our Southern States. Meanwhile the great majority of the troops are being moved back to the hills and camps have been selected with a view to hygienic locations and conditions.

. . . . . .

The care of the yellow-fever patients in and about Santiago has been given in charge of Major Thomas O. Summers of Memphis who has recently arrived there with a corps of twenty-five thoroughly experienced and immune physicians and nurses. This appointment is peculiarly apt as Major Summers is especially well qualified for his work by a practical experience of many years. He was chief of the medical staff at Memphis during the great yellow-fever epidemic of 1878.

. . . . . .

When the medical history of this war shall have been published it will make most interesting and instructive reading, not only for the physician, surgeon, and nurse, but for all who are interested in the running of the machinery that makes or breaks nations. It is practically a trial war in regard to many innovations. For instance, the hospital-ship, or more exactly, the ambulance-ship, has had its first practical trial, and although official reports of the general efficacy of the "Solace" are not yet published, we have it from reliable sources that its value

is beyond the most sanguine anticipations, and by its service many lives have been saved.

. . . . . .

Aseptic and antiseptic surgical methods have been given a fair trial and the success attending them as compared with the results during former wars is as surprising as it is gratifying. It was fully expected that in such a warm, sultry climate as that of Cuba the proportion of deaths to wounds would be enormous, but these expectations, happily, have not been realized. Much credit must be given to the deviser of the plan of having each soldier carry an individual "repair kit." We are assured that many flesh wounds, even though quite serious, when dressed immediately with antiseptic dressings from the wounded man's own emergency case, have healed as readily as a schoolboy's cut finger, without inflammation or suppuration.

. . . . . .

Official reports will no doubt recommend the use of small-bore rifles and high-velocity steel- or copper-encased bullets as the most effective and humane weapons of war. It is conceded that the object to be gained in battle is not the killing of the greatest number of men but their disablement to such an extent that they can fight no more, at least until time enough has elapsed for their wounds to heal. This is the effect of the Mauser and other rifles of this class. The man who is struck receives a clean-cut wound which, while it disables him for fighting, heals quickly and leaves him in a few weeks almost as sound as before. Even when a bone is struck it is not nearly so apt to splinter as was the case when the old Springfield rifles were used.

. . . . . .

The protest made by the *Virginia Medical Semi-Monthly* and other medical journals against the locating of camps on the banks of streams which supply cities or towns with drinking-water, is sound and reasonable and we sincerely trust it will be noted by the War Department. No community in this country would for one day allow a town of 1000 or more inhabitants to empty its sewage and filth into the upper waters of the stream which supplied said community with its drinking-water, and the cases are parallel in the present instance.

. . . . . .

The great number of wounded men as compared with those killed during the action at Santiago has shown the necessity for nurses, and as a result of this experience the War Department is taking steps to provide an extra large number of nurses and surgeons for the Porto Rico campaign.

The gunshot wounds of the one hundred soldiers transported on the "Olivette" from Santiago and admitted to the United States Marine Hospital, Stapleton, Staten Island, July 16, 1898, have been tabulated as follows:

Gunshot wounds, upper extremities	40
Gunshot wounds, lower extremities	29
Gunshot wounds, head and neck	10
Gunshot wounds, chest	5
Gunshot wounds, back	2
Gunshot wounds, penis	2
Gunshot wound, abdominal wall	1

Also the following named injuries:

Sprain of back	1
Contusion of chest	1
Concussion of brain and spinal cord	1

Also,

Effects of heat	4
Enteric fever	3
Inflammation of lymph-glands, groin	1

Among the surgical cases there are compound comminuted fractures:

Of radius	1
Of humerus	1

Compound fractures:

Superior maxillary	1
Radius and ulna	1
Humerus	1
Ulna	1

Also amputations:

Upper third forearm	1
Two fingers	1
One finger	1

Many of the soldiers have malaria and diarrhea.

. . . . . .

As we go to press authoritative information is received by wire regarding the condition of the Spanish sailors held as prisoners at Seavey's Island, Portsmouth, N. H. At present there are only about 250 in the naval hospital. Of these, twenty are suffering from gunshot wounds, and the remainder from bilious remittent fever, intermittent fever, bronchitis, and anemia. Some deaths have occurred, and others are naturally expected among patients who have undergone such hardships as these Spaniards have experienced.

A FEW THINGS TO LOOK OUT FOR IN MANILA.

BY JOSEPH EARLE STEVENS,
OF BOSTON.

To the traveler arrived in the Philippines I would say: "Look out for a Manila northwest wind, especially during the months from June to October," for it rarely comes stealthily stirring the trees without being the harbinger of a typhoon which is making up from the eastward. Not that there are not other things to beware of but that one's ship, one's house, or one's tent generally likes to have previous notice of the approach of squalls.

"Look out for fever in the lowlands surrounding the capital, and, as far as is possible, do not sleep within six or eight feet of the ground," for fevers, both malarial and typhoid, are at home all the year round in the Philippines as well as in other tropical countries, and though the yellow variety is not known, yet the others are insidious enough to bother the strongest. The natives, in order to divorce the floors of their houses from the ground, generally build these structures on posts, leaving a free space of some two yards between the earth and the thresholds of their front doors. The half-castes and foreigners who live in the more elaborate structures in the city or the suburbs desert the ground-floor altogether and use it as a stable for their carriages or a dining-room for hot weather, for there seems to be a dampness, a certain sort of miasma that hangs about the earth, which is the source of much evil, and a commanding officer should think twice before quartering his men in tents pitched on the lowlands of Manila or Cavité. After all the Nipa hut, with its roof of thatch, its frame of bamboo, and its floor of slats is the most rational form of domicile for the Philippines, and temporary barracks for our troops, built up in the fashion of native dwellings, would in any portion of the islands be better than tents pitched on the ground.

Fever is so common among a certain class of foreign residents in Manila that Tom, Dick, or Harry will come into the cool reading-room of the English club, drop down into a chair and say sardonically: "Got the fever again—means another lay off," and while the old-stagers dose themselves with quinin or antipyrin and hang around the office if possible, the newer arrivals buy thermometers, send for the doctor, take ice baths, and either go through a terrific siege, like my friend whose head shrunk so in six weeks that his hats wouldn't fit him during convalescence, or escape with a few days' pull down. In my day it didn't at all pay to lose one's health, either, for there was only one Anglo-Saxon "medico" in Manila, and he had been in the tropics so long that the climate made him forgetful. He would perhaps go into the sick room of a fever-stricken patient whom he had been attending and remark, "Oh, by the way, let's see, what is the trouble with you?" a question which was not always comforting to a sufferer who felt he was on his last legs. But the old residents all knew that when any one's case was really bad there was no cause for complaint and felt easier in being the recipients of such questions as the above than when the sturdy doctor gave them more serious attention.

Colds and dysentery, like fever, are common troubles and it indeed seems curious that the former should be so popular in a hot climate. But such is the case, and the grippe appears to have reached Manila as well as more accessible corners of the world.

It is a great mistake to sleep in silk pajamas in the tropics and new arrivals seem to suffer from colds, more often caught by exposure during the cool hours of the night than at any other time. Flannel sleeping suits are far more sensible than silk or cotton ones and are especially to be recommended, since they absorb the moisture which invariably exudes from the pores of the skin on a warm night and thus protect one from catching cold while he is asleep. Flannel cholera-belts are also most excellent and protect the bowels from drafts of air that often strike home during the dampness of the night or the cold hours before sunrise.

During my whole two years in the Philippines I never suffered from fever or bowel troubles and only twice from bad colds, probably because I took pains to protect myself at night as well as because I was not subject to them.

Smallpox is common in the Philippines and no one thinks anything about it. Nearly all the natives seem to bear marks of the disease and they don't see why they should be vaccinated when they haven't any especial objection to the parent affliction. But any one going to Manila will do well to be vaccinated, since everywhere in the islands he will bump into people suffering from smallpox. There was much of it in the local shipping during the years of my residence in Manila, and the captains of deep-water merchantmen were fearful for their crews. Our office used often to be the scene of a vaccinating-bee, and my partner and I got so proficient that besides doing a hemp business we could take the ink-eraser and some fresh lymph from Japan and inoculate a jolly tar as well as the doctor himself.

Since Manila has been blessed with a good water-supply and big pipes tap the river far up toward the mountains cholera has never made the terrible annual visits it used to in the days when the inhabitants of the capital were wont to use the water right from the dirty river that ran through the center of the town, and when people died faster than they could be buried.

Sprue, that peculiar tropical disease which seems to attack the lining of one's interior and to render it so sensitive that food cannot be retained by one suffering from the malady, is not uncommon in Manila, and is apt to attack certain foreigners whose stomachs are peculiarly susceptible to change of fare. And let him who finds he has sprue get out of the country just as quick as he can, for nothing but a change of climate will effect a cure, and if the trouble is not attended to at the outset the victim will frequently get so weak that he will be unable to get

away at all. In fact, I went out to the Philippines to take the place of a man suffering from sprue and, neglecting to leave in the earlier stages of the trouble, he finally got so weak that he had to be carried aboard the steamer and only fully recovered after a six-months' stay at home. Some may have sprue, leave the islands for Japan or the Pacific coast, and recover from it to come back to Manila, but others are not able to shake it off even by returning home. This irritation of the alimentary canal is an insidious enemy and milk is practically all that a sufferer from sprue can retain within him. Beware of sprue, then, pilgrims to the Philippines, and once you feel those unmistakable symptoms take the first steamer for home.

Sunstroke is apparently uncommon in Manila for one soon gets to respect the sun after a day or two of his attentions. The vital point to protect during one's stay in the direct sunlight is the back of the neck, and a new arrival should be careful about wearing hats that do not shelter this tender region. Practically all of the policemen in Manila as well as the native and Spanish troops wore helmets with extensions behind which fell low over their necks and a sun-hat in the East which is not built with this so-called back verandah has not the protective power it should have. One marvels at seeing many of the natives with their long, thick, straight, black hair, or the Chinese coolies working for hours, hatless, in the vertical sun, but he will do well to marvel rather than to imitate. For letting alone the question of sunstroke it is an admitted fact that over-exposure to the sun is the direct cause of much of the Manila fever.

As the wet season seems, peculiarly enough, to be the healthiest time of the year, so the hot, dry spring months, coming in the lull between the monsoons, are the most unhealthy. Smallpox is particularly active from January to April, and the universal plowing of the soggy rice-fields that comes before the beginning of the rainy season seems to let loose an extra army of fever-germs from the damp soil. In fact some years ago an attempt was made to dig out the old moats surrounding the walled city, filled in with the rubbish of many decades, but so many of the surrounding inhabitants were stricken with malaria or with typhoid that the attempt was abandoned.

In conclusion, the new arrival in the Philippines should guard against fever by sleeping high off the ground, by avoiding an overdose of the sun, and by fighting shy of freshly plowed fields. He should look out for colds and dysentery by sleeping in flannel suits, by wearing a cholera-belt, and by abstaining from too much fruit. He should forestall the attentions of smallpox by being vaccinated before he buys his ticket for the Far East, and above all, at the first suspicion of sprue, he should make tracks for home or the north.

THE WORK THAT IS BEING DONE AT THE UNITED STATES GENERAL HOSPITAL, FORTRESS MONROE, VA.

[Special Correspondence of the MEDICAL NEWS.]

FORTRESS MONROE, VA., July 25, 1898.

IN obedience to orders from headquarters I reported for duty on the morning of July 15th to Major Calvin De Witt, Surgeon United States Army, in charge of the United States General Hospital at Fortress Monroe, Va. Thirty-six years had come and gone since, as an acting assistant-surgeon, I had reported to Assistant-Surgeon C. T. Alexander, United States Army, in charge of the Lawson General Hospital at St. Louis, Mo. Major De Witt received me with as much kindness and cordiality as if he had been an eye-witness of my original entrance as a green boy into the medical service of the United States a full generation ago. At his earliest convenience he showed me his hospital, the various buildings, tents, cooking arrangements, bath-rooms, in a word, everything required for the care and comfort of the sick and hurt soldiers. When upon enquiry, I was told that the entire hospital had been erected in seven days I was simply amazed, and very naturally asked Major De Witt how on earth it had been done. He promptly replied, "Well, we *had to!* And we worked part of the time by electric light."

The patients seem to be doing well as a rule. There are 441 here now. The wounds are for the most part limited to the lower extremities and are from Mauser bullets. Very few seem to be dangerous. Thanks to modern methods, septic wounds and suppuration are conspicuous by their absence. A few cases of mild malarial fever are progressing toward complete recovery. The Mauser bullet-wounds, so far as noted here, seem to be less destructive to the tissues than those produced by the old Springfield rifle-bullet. In the humble opinion of the writer, the medical officers of the hospital originally on the ground have earned for themselves very great honor. For example, on July 13th four acting assistant-surgeons, Drs. Pinkham, Street, Anderson, and McKay, were detailed to superintend the disembarkation of the sick and wounded soldiers, and provide for their care and comfort in the "incipient" hospital. Beginning at 2 P.M., by six o'clock 246 men were all safely and comfortably transferred to their nice, clean quarters, given a bath, furnished with new pajamas, and fed,

in addition to which the history of each had been carefully recorded. On the previous day the four young surgeons had spent their time in preparing dressings, overhauling instruments, and getting things in proper order for hospital service. No nurses had reported for duty, but every patient was seen by one or another of the young men above-named every two hours during the first two days and nights in the hospital. This is a fair sample of the businesslike way things are managed under the master hand of the surgeon in charge.

My attention was called this morning to a case of chorea, the result of shock received in battle without actual wound. The patient lives at 271 Avenue B, New York, and I hope the MEDICAL NEWS will be careful to find out and report his future progress. His name is George W. Bang.[1]

A case of very great interest is that of a private in the regular army. A Mauser bullet entered his neck two inches to the right of the middle line just below the jaw and passing toward the left emerged through the left scapula about one inch from its posterior margin. The wound is perfectly healed, but there is an aneurism which fills the triangles of the neck, and there is motor paralysis of the left arm and complete absence of pulsation in the left radial artery. The patient is a handsome and attractive young fellow, twenty-three years of age, and there is a deep desire on the part of every surgeon here to rescue him if possible from his perilous condition. The result of our efforts will be communicated without delay to the MEDICAL NEWS.

DONALD MACLEAN, M.D.,
Major and Chief Surgeon of Division, United States Volunteers.

THE WOUNDED SOLDIERS AT BELLEVUE HOSPITAL.

ALTHOUGH the number of wounded (twenty-five) now at Bellevue Hospital is too small to allow one to draw final conclusions relative to the surgical results of the battles fought before Santiago, a brief analytical study of the convalescence of these soldiers and the conditions influencing the same may not be without interest. It should be remembered that all were wounded on the first day of the present month, during the first two weeks of which they were treated in the ill-contrived hospitals in or near Siboney. On the 14th instant they were loaded upon transport No. 5 ("Seneca"), which occupied almost one week in reaching New York. The unsanitary condition of the vessel and the neglect to which the men were subjected is at present the subject of official investigation. After four days in the wards of Bellevue we find many of the men daily expecting to be pronounced well enough to take advantage of well-earned furloughs.

The nature of the wounds received can at present be determined only by the patients' accounts and an examination of the existing conditions. The surgeon is able with approximate accuracy to classify them as (*a*) 2 wounds of the skull, (*b*) 3 and perhaps 4 wounds implicating the lung, (*c*) 4 wounds involving the bones or joints, and (*d*) 15 flesh wounds or those in which the involvement of bony or other important structures is insignificant.

The experiment of providing each soldier with an emergency outfit was suggested by Dr. N. Senn, and the results attending its use in the first extensive engagement are accordingly interesting. Of the 21 who had immediate recourse to the outfit, 16 escaped infection altogether, and 5 had more or less suppuration. Among the latter one had a wound of the skull above the eye, from which the bullet was subsequently removed with considerable operative difficulty. But of the 4 who delayed or omitted the use of this dressing, 2 were infected and 2 escaped. When the exposure of these men in the hot and wet trenches, involving a liability to infection almost unsurpassed, is considered, the above statistics cannot be regarded otherwise than a signal victory for aseptic methods. Inquiry as to the first aid supplied by the surgeon shows that 4 men were dressed upon the field without delay, 2 were taken immediately to the first-dressing stations, and there received attention, while 5 others were dressed at the same stations, but not until a variable time (2 to 31 hours) had elapsed, 11 had their first surgical attention at the Division Hospital in from 2 hours to several days, and 3 were not dressed until they reached the general or Red-Cross hospitals.

Subsequent dressings have been applied as the character and condition of the wounds demanded. Some have required daily attention, while others have healed under two dressings.

The present condition of the wounds, taken on the whole, is eminently satisfactory. Fifteen are closed or virtually so, three are clean but not completely filled in, leaving seven which are suppurating. Of the latter, two present a minimum amount of pus, and none is serious save one. This man re-

[1] Inquiry at the address given above elicited the further information that young Bang had been overcome by heat before he went under fire. His own account of the accident is that a shell exploded near him and a fragment passed very close to his right side. Consciousness was immediately lost, and did not return for several days, when he found himself in the general hospital afflicted with violent choreic convulsions. Excepting a slight ecchymotic spot in the dorsal region, no evidences of trauma were found upon him. Since his arrival at home his general chorea has somewhat subsided, but the spasmodic contractions which draw the head violently toward the right shoulder persist, and are apparent even during sleep. He suffers constantly from pain in the upper cervical region, and is excessively nervous and sensitive to unusual noises.

ceived a bullet at the junction of the right seventh rib with its cartilage. It passed through the lung backward and to the right, making its exit three-quarters of an inch behind the middle axillary line and half an inch below the level of the nipples. Prompt use was made of the emergency outfit, and attention was received almost immediately at the first-dressing station. Daily dressings were applied while in the general hospital and thereafter. Pus is now found in the pleural cavity and an abscess of the liver has developed. The patient's temperature is ranging high (104° F.), and his condition is not satisfactory.

OUR PHILIPPINE LETTER.

[From Our Special Correspondent.]

THE MANNER IN WHICH PHILIPPINOS POISON ARROWS—"MALI-MALI"—A REMEDY FOR SNAKE-BITE WHICH WILL NOT APPEAL TO THE FASTIDIOUS.

WITH ADMIRAL DEWEY'S SQUADRON, OFF MANILA, PHILIPPINE ISLANDS, June 17, 1898.

A DISMAL rain has settled down upon the city and the bay, but not even the depressing weather has been able to dampen the spirits of our boys to-day, for the "Baltimore" put out to sea this morning to meet the American transports which are now due from San Francisco. It is hoped that they will arrive before evening, and the marines in the Cavité arsenal and on board the ships in the harbor are full of joyous anticipation and are whiling away the hours by singing "There'll Be a Hot Time in the Old Town To-night."

There was considerable excitement last Wednesday when it was whispered about that Admiral Dewey was going to send a steam-launch commanded by his staff secretary, Ensign Caldwell, past the batteries and up the Pasig River to try to blow up two torpedo-boats known to be hiding there. The "Callao" was to tow the launch to the mouth of the river and there await its return. It would have been an expedition fraught with great danger to every one engaged in it, but Lieutenant Toppen, who was to command the "Callao," and Ensign Caldwell were both fearless and enthusiastic. In perfecting this plan the darkness and the rain were counted on to assist the launch in getting past the batteries and into the river; but the preliminary and possibly unnecessary, reconnoissance of the "Callao" on Wednesday was rightly interpreted by the Spaniards, who in their terror sunk an old transport steamer, the "Cebu," across the mouth of the river, quite regardless of the fact that while they closed the Pasig against the entrance of the launch, they at the same time made prisoners of their own torpedo-boats and rendered it impossible to carry out their plan of making a torpedo attack on the fleet. This they had prepared to do on Tuesday, when they would have been favored by the gale that was blowing, but our ever watchful Admiral sent the "Concord" and the "Callao" to balk their little game.

The local newspapers continue their vituperation of the Americans, and one paper solemnly declares that the recent Spanish victories have completely demoralized us and that President McKinley and his Cabinet are in a state of panic. What these "Spanish victories" were the paper in question does not say, but when the Americans at Cavité, who are many leagues from a truthful newspaper, hear of another "victory" for the Spanish, their hearts leap in their bosoms at the thought that possibly another Spanish fleet has been blown up somewhere. Even the Spanish soldiers are becoming a little doubtful of these stories of disaster to our navy, as I learned yesterday from a fellow correspondent who, in his assumed character of a German sympathizer, manages to keep in touch with the Spanish officers in Manila.

The insurgents have now advanced to a point within sight of the outposts of Manila. Some of these men are decidedly unprepossessing in appearance, and if those people in America who are clamoring loudly for the annexation of the Philippine Islands could spend a short time in the company of these proposed allies and prospective American citizens, they might wonder whether after all the game were worth the candle. To govern these semi-barbarians will not be an easy task, for our weapons will not be those which Spain has used so effectively, her power here having been based principally on her ability to work upon the fear and superstition of the native population through her agents, the priests. The American government has no such agents, and will, therefore, have to depend on other means. In determining this question of government there will have to be taken into consideration the fact that most of the Philippine Islanders are savages who fight with lances and poisoned arrows. I once had the privilege of witnessing the preparation of a number of these poisoned weapons, and as nearly as I can remember the process was about as follows: The poison was made from the bark of two different trees, the names of which I have forgotten. One of the pieces of bark was beaten almost to a jelly, pressed and dried, then moistened and again pressed. Though the man used his bare hands in doing this, he apparently was not injured in any way by contact with the poison. The juice of the bark thus extracted looked very much like pea-soup as it simmered in an earthern vessel over a slow fire. When it had reached the consistency of syrup, a quantity of pulp from the second piece of bark was scraped off and the juice of this squeezed into the syrup over the fire. The juice of the second piece of bark was dark-brown in color and the liquid in the vessel was darkened and changed as soon as the new ingredient was stirred into it. The mixture was then allowed to simmer for some time, until it had attained the consistency of jelly, when it was scraped out of the vessel with a chip and put on a large leaf which had been plentifully sprinkled with ashes. This preparation can be kept a long time without losing any of its strength. To poison an arrow-head a piece of this jelly-like substance about the size of a hickory-nut is warmed and rubbed all over the point, which can be used repeatedly without the poison losing its virtue. The natives also have daggers with sharp-pointed blades about four inches wide and a foot long, which they call *bararaos*. They are very dexterous in the use of this weapon, and

if they can lay hold of an adversary by the hair, they cut off his head with one sweep of the arm and carry it home as a trophy of war.

Among the natives there is occasionally found a peculiar nervous disease called *mali-mali*, the victims of which seem to be impelled by an uncontrollable impulse to imitate the movements of any one they see before them. Sometimes the disease will lie dormant while the victim goes quietly about his work, but if frightened or excited in any way he will immediately begin to imitate every motion of any person who attracts his attention. If a person suffering from this disease becomes angry he shrieks and raves like a maniac, at the same time continuing his mimicking performances. Old women are the most common victims of *mali-mali*, though men are sometimes attacked. Some people believe that the imitation-mania, as it is sometimes called, is always assumed and that the pretended victims can control their antics if they try, as they are often attacked in the presence of Europeans from whom they hope to obtain alms; but there is no doubt that the symptoms of this disease are generally real, and that such a disease exists is certain.

The natives have a strange cure for the bites of snakes and mad-dogs. The first excrement of a new-born infant is carefully preserved and is believed to be highly efficacious as a remedy for snake-bite, but it must be used both externally and internally and immediately after receiving the bite. I have been informed by a physician who has spent many years in the Philippines that fully a quarter of the children of natives die within two weeks after their birth. He expressed the view that this great mortality is probably caused by the impure air which is always found in the lying-in chambers of the native women. No matter how hot the weather, the doors and windows are hermetically sealed, in order to keep out the evil spirit called the *patianac* which, as I explained in a former letter, is supposed to make all sorts of trouble if it can get access to a woman in labor. But the great mortality among infants has probably a deeper cause than this; it doubtless lies in the constitution of the natives, who do not seem to be of hardy fiber, for if forced to suffer from hunger and thirst they soon sicken and die, and fully half of them have some kind of bronchial trouble.

The old Buddhist belief that the soul leaves the body during sleep is shared by the Philippine Islanders, who are very careful in waking a sleeper to do so gradually and by slow degrees, so that the soul may not be called back too suddenly and rudely into the body which it has for a time deserted. No greater insult can be offered a native than to wake him suddenly or to walk over him as he lies asleep. They dread nothing more than to die during sleep, and their worst curse is "May you die sleeping."

The sense of smell is abnormally developed in the Philippinos, and they can tell to whom any article of clothing belongs by simply smelling of it. The manner of kissing practised among some of them is peculiar. Instead of pressing the lips together, they press the mouth and the nose against the cheek of the person caressed and draw a long, deep breath. In asking for a kiss they do not say "kiss me," but "smell me."

The natives fear many things, both natural and supernatural, and in the Island Sámar the huge bats are regarded by them with feelings of awe that are almost reverential. The caves in the mountains are nearly all inhabited by these creatures, and the natives stand especially in fear of what they call "Calapnitan," or the "Lord of the Bats." It is great sport to go bat-shooting, and the great, uncanny creatures are game to the end, hissing and snapping at any person who wounds them. In the daytime they may be seen hanging asleep from the branches of trees, but as soon as night comes on they spread their wings and fly about like great vampires, filling nervous people with horror. Bats suckle their young like mice, and I remember that on one occasion I shot a mother bat who was engaged in feeding her family. The little creatures did not interrupt their dinner but continued to stick to the dead mother until their hunger was satisfied or the milk exhausted.

Food is growing more scarce in Manila every day. Horse meat sells for $2 a pound, and other meat is now a luxury only within the means of the rich. The insurgents took the blockhouse at Meypajo yesterday, and they have succeeded in effectively penning up the Spaniards in the old walled city of Manila, where they are huddled like sheep, all the Spanish families and hospital patients having been brought inside the walls. It is rumored that torpedoes have been placed by the Spanish in the roads leading into the city, but experience has taught the Americans not to fear the Spanish torpedo. If no more serious obstacle than that blocks our way, the taking of Manila will be easy; but there is Admiral Von Diederichs out in the harbor with his fleet of German warships, waiting, like a vulture for its prey, for an opportunity to snatch his "share" of the prize which Dewey won for America.

CLINICAL MEMORANDUM.

SUPPLEMENTARY ANTITOXIN REPORT.

By I. H. LOPEZ, M. D.,
OF PHILADELPHIA.

ABOUT a year ago it was my privilege to read a paper before the Associated Physicians and Surgeons of the Charity Hospital on "The Treatment of Diphtheria with Antitoxin."[1] My report embraced thirty-seven cases and twice that number of children immunized. The purpose of this paper is to supplement my early report with experience I have since had with the remedy in two institutions with which I am associated.

A child was admitted into one of the Homes, October 23, 1897. On November 21st the mother visited the institution bringing with her a jacket which the child subsequently wore. A week later he was taken down with diphtheria. Thirty-five other cases promptly followed, of which thirteen were sent to the Municipal Hospital and twenty-three treated in the institution. Of the first, six died; and of the latter, one. All had received antitoxin treatment, but some of those removed to the hospital de-

[1] MEDICAL NEWS, February 6, 1897.

veloped grave complications, measles, scarlet fever, etc., which broke out in the hospital wards and were the cause of death, as certified in the death certificates. Those sent away for treatment were the first cases that appeared. The outbreak was subsequently traced to the home from which the mother had brought the apparently innocent little jacket. No other cases appeared in this institution until January 18, 1898, when diphtheria developed in a new arrival, one week after admittance. Several other cases immediately followed, so that a widespread epidemic was imminent, In this outbreak none of the children was removed, but all that had been in any way exposed, 110 in number, were promptly immunized. The doses administered ranged from 250 to 500 units according to the age of the child. Four or five of these children had sore throats with small patches on the following day. Each of these and all that had already developed the disease received 1000 units each. The result was a prompt recovery in every instance and no new cases have appeared in the institution since.

About the same time forty-one cases of diphtheria appeared in rapid succession in another institution. All were more or less complicated with measles and scarlet fever. The four initial cases did not receive the serum treatment and all died. The remaining thirty-seven cases received antitoxin treatment and but two died. It is worthy of note that, deducting the fatal cases, without a single exception, the 174 antitoxin-treated cases developed no sequelæ, either those receiving curative or immunizing doses. Thus far the claims made for diphtheria antitoxin, that it is an efficient non-toxic, non-depressant antidote for the poison of diphtheria, have in my experience been fully realized. When given early and in adequate doses, it will promptly check the disease, after which we have only to contend with the damage done before the poison was neutralized. This damage always varies according to the virulence of the absorbed toxins and the length of time they have been permitted to remain unchecked. During the recent prevalence of diphtheria in our city I was enabled to test more fully the merits of antitoxin, and used it fearlessly in every case, old or young, without the least unfavorable symptoms, but with recovery in every instance. On the other hand, I could cite six cases to which I was called only at the last hour and in which the remedy had not been used. In two of these the attending physician had been having cultures made for four or five days without being able to recognize the disease. In three the physicians had had no experience with antitoxin, and feared unfavorable results. In one instance the mother had treated the child for croup with goose grease and molasses. The result in the six cases was strictly uniform—"they sleep with their fathers."

MEDICAL PROGRESS.

Mortality after Amputations.—SCUDDER has recently published some figures (*Boston Med. and Surg. Jour.*, June 30, 1898) showing the mortality after amputations during the pre-antiseptic days, in the transition period, and at the present time. They will be read to-day with interest, even though there is far less of amputating in the military operating-tent than there once was. The columns of figures which, unfortunately, are not mutually exclusive, are as follows:

TABLE COMPARING MORTALITY PERCENTAGES OF MAJOR AMPUTATIONS DONE AT THE MASSACHUSETTS GENERAL HOSPITAL.

	1821–1870	1870–1890	1885–1896
1. Amputation at the Shoulder-joint.			
Traumatic, primary	53.33	50.00	31.57
Pathological	27.27	00.00	00.00
2. Amputation of the Arm.			
Traumatic, primary	19.44	12.19	22.22
Traumatic, secondary	.....	.....	18.18
Pathological	12.50	16.12	11.11
3. Amputation of the Forearm.			
Traumatic, primary	24.13	22.99	6.00
Traumatic, secondary	.....	.....	0.00
Pathological	14.81	14.00	8.57
4. Amputation of the Thigh.			
Traumatic, primary	42.37	47.54	35.21
Traumatic, secondary	60.00	28.50	37.00
Pathological	20.98	23.28	17.55
5. Amputation at the Knee-joint.			
Traumatic, primary	60.00	60.00	50.00
Pathological	36.36	50.00	00.00
6. Amputation of the Leg.			
Traumatic, primary	34.37	27.73	13.66
Traumatic, secondary	36.41	21.43	7.14
Pathological	12.60	13.78	13.55

At the first glance one is rather surprised that there is not a greater difference between the former days and the present, but upon second thought attention is directed to the fact that antisepsis and perfected technic can never avert death from concurrent causes, as so often happens in the pathologic as well as in the traumatic cases of amputation. Then, too, the very fact that amputation is now looked upon as a last resort makes of it an operation for the worst cases only, and the mortality is proportionately heightened. Incidentally these figures are an eloquent testimonial to the work done in that famous old stone building in Boston that knew so well a Bigelow and a Warren long before carbolic acid and bichlorid of mercury came to mark the line between past and present.

The Operative Treatment of Brain Hernia.—MOELLER (*Deut. Zeit. f. Chir.*, vol. 48, p. 23) thinks that the common opinion that a hernia of the brain will probably end in death either with or without surgical treatment ought to be so far modified as to exclude those cases in which there exists a distinct pedicle which has become obliterated during intra-uterine life. Upon such a subject one may operate with a good chance of success, as is shown by a case successfully so treated by him. What the chances in general are is shown by the record of Von Bergmann's clinic in Berlin, where of 23 patients, 3 recovered from operation, 5 died from operative attempts, and 12 died without any surgical measures having been taken. It follows naturally that the prognosis in meningocele is better than that in case of encephalocele, which in turn is better than that in hydrencephalocele.

Tuberculosis of the Penis.—GASTON (*Centralbl. f. Chir.*, May 23, 1898) describes a case of tuberculous ulcer of the penis which had all the appearances of a hard chancre. The history showed, however, that there had been none of the usual manifestations of syphilis, and that the

trouble had existed for seven years; and further, that the patient suffered from tubercular lesions in other parts of the body. Microscopic examination of a section of the growth left no doubt as to its nature, although no tubercle bacilli were made out. The penis was excised and the stump healed well. Lupus subsequently developed in one of the patient's hands.

Strongest Antitoxin for Rabies Yet Discovered.—FRANTZIUS (*Centralbl f. Bacter.*, etc., May 13, 1898) finds that the bile of an animal suffering from rabies differs from the other fluids of the body in that it does not contain poison. Further tests with such bile showed it to contain an antitoxin against rabies more powerful than any form of antitoxin yet described for this disease. This is not a property of all bile, as investigation showed that the normal bile of cattle, sheep, swine, etc., possesses no antitoxic value. This antitoxin in the bile of animals suffering from rabies is therefore developed during the disease, and manifestly for the purpose of protecting the affected animal against the disease.

THERAPEUTIC NOTES.

Ichthyol in Pulmonary Tuberculosis.—COMBEMALE and DESOIL (*Echo Med. du Nord*, April 17, 1898) report that during fourteen months all the phthisical patients in the Charité Hospital at Lille were treated with ichthyol. Observations were made upon 110 patients who were treated with this drug to the exclusion of all other medication for periods varying from one to six months. Pills and capsules of ichthyol were found to be the least objectionable preparations. The daily dose at the beginning of treatment was 1 gram, but this was gradually increased to 4 grams unless diarrhea intervened, which was too strong to be controlled by moderate doses of dermatol. This happened in very few instances. If these doses of ichthyol were quickly tolerated there was a prompt improvement in the general health of the patient, as manifested by the disappearance of night-sweats, a gain in weight and strength, a reappearance of the menses, etc. This desirable improvement rarely manifested itself before the end of a month, and it did not occur at all in two-thirds of the patients. Expectoration was almost invariably lessened in amount and made more fluid, so that coughing was easier.

On the Washing of Eczematous Hands. — UNNA (*Monatshefte für prakt. Dermat.*, June 1, 1898) says that it is quite possible to cure eczema of the hands without compelling the patients to give up their occupation, even though they may be engaged in such work as cooking, baking, bricklaying, or other occupations in which the hands are constantly filled with dust. It is not the washing of the hands which increases the eczema; on the contrary, the careful cleansing of the skin is favorable to the cure of that trouble if the skin is not thereafter exposed to the air or to some other irritant. Hence he makes it the rule that a thorough washing of the hands in such patients shall take place in the evening, and that the skin shall be rubbed with some oleaginous substance and protected from drying by an impervious covering of wash-linen or rubber. In the morning the hands are simply wiped clean but not washed. Before meals the hands are oiled and wiped, or if they are so dirty that washing is unavoidable, they should first be oiled, then washed with soap, and immediately wiped and thoroughly oiled again. In brief, the treatment is included in the two precepts: No washing without a subsequent oily bandage; and the substitution of a thorough evening cleaning of the hands for the usual morning washing.

A Case of Traumatic Tetanus Cured by Intracerebral Injections of Antitoxin. — CHAUFFARD and QUENU (*La Presse Med.*, June 18, 1898) report a case of traumatic tetanus in a lad, aged sixteen, which they treated successfully with injections into the brain of antitoxic serum. Two fingers were crushed by accident. Four days later there was edema and redness, but without pain or fever. Fourteen days after the injury the swelling had not subsided in spite of constant wet dressings, and stiffness of the lower jaw was noticed for the first time. Two days after that as the condition of the patient was growing rapidly worse, a small hole was made with a trephine in the bared skull, 3.5 inches above the right external orbital process, and about thirty minims of concentrated antitoxic serum was injected to a depth of two inches into the brain. This procedure was repeated on the left side. Both wounds were sutured. There was no bleeding or unpleasant symptoms, and the condition of the patient improved. Upon each of the four succeeding days there was made a subcutaneous injection of about 5 drams (20 c.c.) of antitoxic serum and a pint of artificial serum. The patient recovered entirely. During the convalescence there were the common unpleasant effects of the use of large injections of serum, such as pruritus, pains in the joints and muscles, etc.

Serum to Prevent Death from Burns. — TOMMASOLI (*Centralbl f. innere Med.*, June 25, 1898) recommends the injection of artificial serum to prevent death from extensive burns. The patient upon whom this method was first tried died from the effects of his burns, but the second one was saved, after having received injections of from eight to sixteen ounces of the serum daily for a number of days. By experiments upon animals the writer was also able to demonstrate the power of the serum to save life after burns. Two out of six rabbits whose hind quarters were severely burned recovered, while four control animals died. Eight out of ten dogs similarly burned recovered, while the control animals all died. In the light of this rather imperfect experience the writer does not hesitate to recommend the method for further trial.

DIPHTHERIA ANTITOXIN PATENTED.

WE believe that the information that Behring has not only applied for but received a United States patent for the production of diphtheria antitoxin will come not only as a surprise but also as a disagreeable shock to the readers of the MEDICAL NEWS. On January 11, 1895, a patent was applied for in the following terms: "Be it known that I, Emil Behring, a citizen of the Empire of Germany, have invented certain new and useful improvements in the manufacture of diphtheria antitoxin of which the following is a specification: My invention consists in the production of a substance called 'diphtheria antitoxin' by means of which people may be immunized against diphtheria and people suffering from diphtheria may be cured, etc." This patent after having been several times refused was finally granted June 21, 1898. We learn that more patents have been applied for by Behring and other prominent bacteriologists of Germany for bacteriologic products in which they have made some improvements. Behring's application for a patent is apparently only the beginning of a general attempt by some German investigators to reap direct money reward for any discoveries which they may make or for which they may be able to convince the Patent Office of the correctness of their claims. This new attitude among some who have previously done merely scientific work may turn out to be a matter of great importance. Lest we judge Behring unfairly let us consider what portion of credit belongs to him and what to others for the discovery of diphtheria antitoxin and its application to disease.

Klebs was the first to describe the bacilli in the tissues of those sick with diphtheria, Loeffler to demonstrate their etiologic relation to diphtheria and that repeated injections of them produced immunity. Roux showed they developed in bouillon a substance called "toxin" which caused after injection all the constitutional symptoms produced by the absorbed poisons from the diphtheria bacilli in the pseudo-membranes. C. Fraenkel equally with Behring, repeated Loeffler's experiments and showed that injections of toxins as well as of living bacilli would produce immunity. Meanwhile many following the directions of Pasteur produced in animals immunity to many diseases by cultures or toxins, and Richet and others discovered that the serum from some of these immune animals when injected into other animals conferred immunity. Behring and Kitasato working together were the first to prove that the serum of animals immunized to tetanus contained immunizing substances, and at the same time Behring, Wernicke, and Aronson found the same to be true of animals immunized to diphtheria, and suggested that the serum might be found to be useful in diphtheria in man. A trial of a serum weak in antitoxin on a few subjects seemed to have some beneficial effects. Behring and Aronson in Germany, and Roux in France, now produced antitoxin on a larger scale. To Roux's experiments we owe the first convincing proofs of the serum's benefit. After Roux's reports, and the general use and manufacture of antitoxin, Behring applied in Germany and elsewhere for a patent for its production.

Behring's patent therefore covers much thought out by others, such as the injecting into animals of the diphtheria bacillus (Loeffler's discovery) or of its toxins (Roux's discovery) into horses (Roux's suggestion). Not even Behring would deny that without the use of the diphtheria bacillus no antitoxin could be produced, and that without the use of toxins no high-grade antitoxin could be obtained. From the

above we see that although the first discovery, or at least the first publication of the fact that in the blood of immunized animals there is a substance which neutralizes the diphtheria poison, is and probably should be credited to Behring, yet it is equally true that if Loeffler and Roux had not published their discoveries Behring would in all probability not have made his, and if they had patented them Behring would have been absolutely prevented from making use of his discovery. It is also certain that if Behring had not hit upon this discovery when he did others would have done so, as the principles had been established for some diseases already, and all were being experimented with to determine in which the curative substances would be in sufficient amount for therapeutic purposes.

Behring has strained the intent of the patent law in obtaining an instrument for appropriating to his own advantage the disinterested investigations of scientists who supplied the data and even the suggestion he adopted. They gave their results freely to mankind without a thought that the benefits directly derivable would be restricted for the profit of an individual instead of being freely distributed for the relief of sufferers from a deadly disease. Science herself suffers from an abandonment of the liberal principles which are the glory of her votaries. The whole patent system is by no means secure in public favor, and in proportion as antitoxin proves to be a public necessity, and Behring's gain increases, just so far will he furnish the most powerful argument yet presented for the abolishment of the entire patent law.

If men who have previously been working for purely scientific purposes desire to work instead for money rewards, no one can object so long as they frankly state their purpose at the beginning. To seek applause first for disinterested work and then to grab for a monetary recompense is not creditable. If this change of purpose ever becomes general it will be, we believe, a great misfortune to science and the race. It will subject all scientific workers indiscriminately to the suspicion of being open to the criticism of being possibly biased by personal advantage. Those who are still guided by different and higher aims, will be included in this distrust, and, indeed, be driven to patent all discoveries of new facts, so that those eager for gain may not seize, and, after giving them a practical application, patent and control them. We are hopeful, however, that the best men will still be satisfied with the old rewards of interest in their pursuits, the fellowship of kindred workers, and by the honor and position which come from successful effort. Money brings much that is very desirable, but there are some things too valuable to sacrifice to it. We trust for the good of the sick that this patent will be tested and overthrown in the courts.

PUBLICATION OF SCHENK'S THEORY OF SEX.

THE fulfilment of the widely advertised promise of Professor Schenk to give to the medical world the full details of his theory in regard to sex has been received in almost absolute silence. The original monograph in German and the authorized English translation have scarcely been noticed by the medical press, or even by the daily papers, which devoted pages to the Court Physician some months ago. The celebrated author lends the weight of his testimony, such weight as it has, at least, to the theory of sexualization known as cross heredity. He says the determination of sex is a question of metabolism on the part of the mother; if she is poorly nourished her ova will be so badly developed that they cannot attain to the splendid possibility of becoming male embryos, but are only fitted to grow into females. If, on the other hand, the mother is in a condition of perfect metabolism, it is possible for an ovum to evolve cells capable of forming the parts of a male child.

Schenk believes that he can determine the state of the metabolism of a woman by the examination of her urine. If he finds that there is even a minute quantity of sugar in the urine it is evidence that the metabolism is not perfect, and there consequently is fear that a female child may result if she becomes pregnant. The practical application of the theory consists in so altering the diet of the mother that her metabolism shall be perfect. It is needless to say that the dieting must begin some weeks before fecundation, and must be continued some weeks thereafter, until the sex of the embryo has become well established. In the words of the author, "The treatment consists in giving the mother a highly nitrogenous diet, with fat, and adding only so much carbohydrate as is absolutely necessary to prevent its want being felt."

Schenk says that at present the "wish to have fe-

male children is a desire, for the gratification of which it is not at present possible to give any directions." But, indeed, it is a poor rule which will not work both ways. Why not cut down the albumens and fats and give starches and sugar when daughters are longed for? But what woman will want daughters if they are to be taken as proof of her own decay?

Confirmation of this simple theory may now be looked for on all sides. It is so simple that every materfamilias-elect may put it to the test—eggs instead of oatmeal, butter without bread, and no candy for four months, and the thing is done! Who knows but that another year may see Schenk lunch-rooms in all the department-stores!

THE PERNICIOUS MALARIAL FEVER OF THE TROPICS.

WITH the departure of our troops for active service in the Philippines and West-Indian Islands, and the certainty that we are about to enter upon permanent tropical colonization, great interest has been aroused among the medical profession with reference to the dangers to be encountered by our soldiers in those so-called trying climates. Distance often lends not only enchantment, but fear, especially when connected with diseases of foreign climes.

When the Nicaragua Canal Company inaugurated its work in 1889, so great was the fear of a high death-rate among its employees that extraordinary efforts were put forth in the way of prophylaxis. Nor was this fear unjustifiable; the experiences encountered on the Isthmus of Panama, where "every railroad tie represented a death," the demoralizing death-rate from yellow fever, pernicious remittent malaria, etc., not only among canal employees, but the foreign colonists of Panama and Colon, furnished sufficient grounds for apprehension; and yet the death-rate along the line of the canal from climatic diseases was only seven-tenths of one per cent., a percentage so small as to stagger those who believed that the diseases of the tropics are far more fatal than those with which they are familiar at home.

This low death-rate was the more remarkable in that it did not represent the whole force of men employed, but those actually on the hospital rolls. The climate of Nicaragua deserves large credit for this low mortality, but the policy of the Canal Company was primarily responsible for the good health of its men. While the other departments were weighted down by an abundance of army and navy red tape the administration of the medical department was comparatively untrameled in the hands of the Chief Surgeon. His requisitions were promptly filled and without questions; his judgment on professional matters was considered paramount; his positive orders were simply, "prevent sickness when possible, look after the comforts of the sick, and keep down the death-rate;" his relative one, "as economically as possible." Such liberal orders, such freedom from red tape, unfortunately cannot be attained in our Army, and therefore there must be a relatively larger fatality from climatic diseases; but it would be unjust to charge these results to climate alone. With the exception of yellow fever, tropical dysentery, tropical diarrhea, and the pernicious types of malarial fevers, our troops in the West Indies are not liable to encounter any diseases with which American physicians are not more or less familiar.

Remittent malarial fevers are far more common than the intermittent form; they are more intense in their onset than in temperate zones and require more energetic and prompt treatment, but if intelligently handled, in the vast majority of cases will respond readily to treatment. The most important point for our surgeons to insist upon is the early recognition and treatment of malarial fevers in their various forms. In the Nicaragua Canal hospitals the average duration of cases of remittent malarial fever was five and one-half days; had these patients been neglected in the incipiency of their attacks they would probably have been ill twelve or fourteen days and many deaths would have occurred.

In the tropics a physician does not depend upon small doses of calomel and quinin, nor can he wait for the action of a cholagogue before administering the last-named drug. An active sudorific, followed at half-hour intervals by three 10-grain doses of quinin, which in turn should be followed within two or three hours by a large dose of calomel, rhubarb, and soda, will nip in the bud most cases of remittent fever, so that a daily dose of from 20 to 30 grains of quinin for three days thereafter will be followed by convalescence.

Far more dangerous to the patient than yellow fever, is pernicious malarial fever, especially in the form known as malarial hematuria. This undoubtedly is the disease known as the "black-water fever" in Africa, and a careful perusal of its history will, I believe, show that the administration of quinin, contrary to the report of Koch on his recent trip to Africa, has nothing to do with its production. Those familiar with malarial hematuria in our Southern States and Central America know that generally the hematuria antedates administration of the drug, and disappears when the patient is thoroughly cinchonized. If the milder forms of remittent fever are early recognized and promptly treated, the pernicious forms will not be encountered, for it seldom develops as a primary form; there is always a history of recurring, and generally neglected, malarial attacks, and seldom does it develop in a new arrival in the tropics.

The statement that "malaria, even untreated, in any single attack is a self-limited disease, and successive attacks are milder and milder," unfortunately will not prove true in the West Indies. On the contrary, immigrants from northern climes if properly treated during their first, second, and third attacks of malarial fever, show greater resisting power during the second, and seldom have more than the three attacks. If neglected, each successive illness becomes more severe, and finally they develop the dreaded pernicious type.

Pernicious malaria occurs only in those persons who have been a long time subjected to slow malarial infection, without the proper administration of quinin. So closely does the appearance of the patient resemble that of one with yellow fever that superficial observers have named the disease "highland yellow fever." The distressing symptoms are hematuria, intense nausea and black vomit, extreme thirst, frequently repeated chills of a congestive character, and, at times, sinking turns amounting almost to syncope. The remaining symptoms are those common to other cases of remittent fever; like yellow fever it has an algid, icteric, and hemorrhagic variety. In the algid form there is a marked difference between the rectal and sublingual temperature, amounting at times to 3° F. The treatment of this disease must again be different from that of the mild forms of malarial fever. Promptness, energy, and unremitting watchfulness are desiderata without which the patient will be lost.

Much discussion has lately taken place as to the advisability of administering quinin in these conditions, but I believe the preponderance of evidence to be in favor of immediately thoroughly cinchonizing the patient by hypodermatic doses of quinin and establishing free diuresis and catharsis. In a majority of these patients thorough cinchonism will be evidenced by fall of temperature and amelioration of other symptoms.

Prophylaxis against tropical malarial fever in our camps should consist of changing the clothes before retiring as night, (unfortunately often impossible), avoidance of constipation, and a daily ration of quinin, to which whisky should be added when the subject has been exposed to rain. Sleeping in shacks or in tents with the sides open, and as far as possible selecting for camps high sites exposed to wind and sunshine should be encouraged. Hammocks should be swung at least three feet from the ground; in more permanent locations beds constructed of split limbs of trees are better than hammocks. Mosquito-nettings should always be used, and as the mosquito of the tropics is often smaller than his fellow of the North, a very fine mesh is indispensable. Add to these precautions a careful, systematic medical supervision of water-supplies, kitchens, and diet, a daily inspection of each company by a medical officer, and, finally, rejection at recruiting-stations of men with positive histories of malarial infection, and the invaliding home of all patients who respond only temporarily to treatment and this bogey of the tropics will be robbed of half its terrors.

J. Edward Stubbert, M.D.

ECHOES AND NEWS.

Marseilles Hospitals.—M. Louis Salvator, a resident of Marseilles, has bequeathed his entire fortune amounting to nearly $1,500,000 to the hospitals of that city.

A New Dean for Johns Hopkins Medical College.—At the beginning of the next collegiate term, Dr. Welch will resign his position as dean in favor of Dr. Osler.

Prevention Cheaper than Cure.—*The Hospital* is authority for the statement that the recent epidemic of typhoid fever at Maidstone, England, cost the taxpayers of that village $85,500.

The London Hospital Bazaar.—The bazaar recently held

in London for the benefit of the London Hospital, realized the enormous sum of $100,000. It was held at the Hotel Cecil and lasted two days.

Red-Cross Nurses.—Since General Sternberg has given his consent to the employment of Red-Cross nurses in the military hospitals the society has been most active in supplying nurses, both male and female, experienced and inexperienced, immune and non-immune.

A New English University.—For some time past the establishment of another university to be located at Birmingham has been agitated. It has recently received an endowment of nearly $500,000. The proposed university is to be known as the Midland University, and will include a college of medicine.

Honors to Nurses.—The eleven nurses who devoted themselves to succoring the typhus-stricken peasantry of Inniskea, Ireland, during the epidemic of 1897, have, by the sanction of the Queen, been enrolled Honorary Serving Sisters in the Grand Priory of the Order of the Hospital of St. John of Jerusalem in England.

Medical Department of the University of Denver.—The following professors have recently been appointed in the faculty of the above-named institution: Dr. Carroll E. Edson, professor of therapeutics; Dr. Hobart E. Warren, associate professor of anatomy in charge of the department; Dr. T. J. Gallaher, professor of laryngology and rhinology, and Dr. I. B. Perkins, clinical professor of gynecology.

The Royal Army Medical Corps.—Owing in great measure to the commendable efforts of Lord Lansdowne, the medical service of the British Army has at last received rank and recognition somewhat in accordance with its relative importance and merit. It will henceforth be placed beside the Royal Engineers and Royal Artillery, and the hope is expressed that it will now attract candidates capable of sustaining the former prestige of the service.

Typhoid in the Camp at Jacksonville, Florida.—Regarding the slight outbreak of typhoid fever in the Seventh Army Corps, Colonel Maus, the chief surgeon, says that no local causes had anything to do with the disease in any of the cases. The Virginia and Mississippi regiments were infected by the water at their State camps respectively. One company of the Illinois Regiment partook of tainted meat and the men were doubtless poisoned thereby.

The Memphis Lancet.—Number 1, Volume I. of this journal for the month of July, 1898, is duly received. While Memphis was previously the home only of the *Memphis Medical Monthly*, the *Memphis Lancet* is a welcome addition to the family, and hereafter Memphis will have two medical journals. The *Lancet* starts under the most flattering auspices and promises to take a high place in the estimation of the profession.

History of Medicine.—At the Congress of Scientists and Medical Men, which will hold its next regular meeting in Düsseldorf September 19th to 24th, it is intended to have an exhibit illustrating the general history of medicine. Medical antiquities from Phenicia, Egypt, Babylon, and Medo-Persia, from Troy, Greece, Japan, China, India, Etruria, ancient Rome, as well as medieval and modern Europe will be so arranged as to present a complete panorama of medical progress since the dawn of civilization.

Medical Education for Women in England.—English opinion as to woman's proper share of the fruits of the tree of knowledge is indicated by the fact that science laboratories for the London School of Medicine for Women have been constructed by public donations and opened for use. The dedication exercises were presided over by Her Royal Highness the Princess of Wales, who, as *The Hospital* says, stands in the eye of the British public as the representative of all that is pure and true in womanhood.

The Hospital-ship "Relief."—The hospital-ship "Relief," which arrived in New York Harbor on the 23d inst., presents a striking contrast to the condition on board the "Seneca" which preceded her. On the "Relief" every detail was perfect, every patient was provided with a cot, and there was an efficient corps of trained nurses and surgeons and an abundant supply of medicines, appliances, and delicacies, in fact, everything that a hospital-ship should have for the care and comfort of the Nation's sick and wounded.

To Honor Joseph O'Dwyer and to Commemorate His Work.—At a meeting of the section of the American Medical Association on the Diseases of Children, at Denver, Colorado, June 7–10, 1898, by unanimous vote, a memorial committee was appointed with suitable powers to collect money in conjunction with other similar committees, for the purpose of commemorating the life and work of Dr. Joseph O'Dwyer. The committee is composed of Dr. Louis Fischer, New York, Chairman; Dr. J. P. Crozer Griffith, Philadelphia, and Dr. F. E. Waxham, Denver, Colorado.

Medical Advice by the Clergy.—The Roman Catholic Bishop of Augsburg, Germany, has recently made a communication to the clergy of his diocese on the increasing tendency of the clergy to give advice in cases requiring medical treatment—a practice which he condemns and charges that it be avoided. The action of this bishop is the more pertinent, since the home of the late Father Kneipp and his successors is within his diocese. Would that the American clergy, both Catholic and Protestant, might receive a similar rebuke and that their penchant for quack nostrums might be forsworn.

Accident to the Prince of Wales.—A strong undercurrent of apprehension is said to exist in England regarding the ultimate result of the fracture of the patella recently sustained by the Prince. The condition of his heart and kidneys renders the use of anesthetics dangerous, and the mistake of sending him by slow train up to London from the country seat where the accident occurred permitted the capsule of the joint to become so distended with blood as to prevent approximation of the fragments

of the patella except by radical procedures. Fears are expressed that the Prince will always be lame.

Condition of the Yellow-Fever Invasion. — At the present writing not a single case of yellow-fever exists within the boundaries of the United States, and it is a remarkable fact that not a single case has appeared among either the prisoners or the soldiers who have been brought back from Cuba. General Shafter reports that there are 1896 soldiers in the hospitals about Santiago, and that of these about 150 have yellow-fever. The disease, however, seems to be very mild in character, and the few deaths which have occurred in his army have been due more to typhoid fever and intermittent fever than to anything else.

Responsibility for the Transport "Seneca."—The reports regarding the condition of the "Seneca" which recently arrived in New York Harbor with 125 sick and wounded soldiers from Santiago has aroused great indignation in all quarters. The ship-surgeons and nurses report that they were almost destitute of proper medical and surgical supplies, and were only able to care for the sick and wounded by the most ingenious makeshifts. Surgeon-General Sternberg has ordered an official investigation based upon these charges, so that we shall soon know the exact truth in regard to the condition of the ship and the supplies on board, as well as to be able to fix the responsibility where it rightly belongs.

Dr. Donald Maclean of Detroit, Michigan, who recently received an appointment as Major and Chief Surgeon of Division in the Volunteer branch of the service writes most interestingly in this number of the MEDICAL NEWS on the facilities at Fortress Monroe, Va., for the care of the sick and wounded soldiers from the front. As a former President of the American Medical Association, and as former Professor of Surgery at the University of Michigan, Dr. Maclean's circle of friends in the profession is probably second to that of none in this country, and it cannot but be a source of satisfaction that under his skilful supervision the men who have been wounded in their country's cause will receive the care and attention which they so justly deserve.

A Correction.—Our attention has been called to a statement in our "Philadelphia Letter," published in the issue of July 9th, in which the Baltimore Medical College is apparently accused of improper practices. This is an error for which we tender apologies. It is due to the fact that the article *the* was used instead of the article *a*, and should read, *a* Baltimore medical college. We are assured by our correspondent that the circumstance as described is true in every particular, and that *a* Baltimore college is the culprit. We regret the oversight by which an apparent stigma was placed upon a most worthy institution. The Baltimore Medical College is a member of the American Association of Medical Colleges. With the year beginning October 1, 1898, a four-years' course will be required for graduation.

The Increase of Suicides in Italy.—Suicide in Italy has greatly increased during the last few years. In 1897 the increase, compared with the ten preceding years, was more than 50 per cent. The total number of suicides for that year was about 2000, which corresponds to a "voluntary mortality" of 6.41 for every 100,000 inhabitants. Of this total 1404 were men and 596 were women. Married persons numbered 810, unmarried 949, widowers 177, and widows 61. The greatest number of suicides took place in the three months of spring and those of summer, being respectively 614 and 572. Professor Lombroso attributes the increase in the number of suicides to the greater difficulties of supporting life, to burdens which weigh each day more heavily upon the country, and to despondency caused by the utter hopelessness of the future.

The A. M. A. Code of Ethics.—Dr. W. O. Bridges in his recent presidential address before the Nebraska State Medical Society expressed the following sentiment: "I must dissent from the opinion expressed at the semi-centennial of the American Medical Association in the presidential address of our distinguished surgeon, Dr. Senn, when he said the code of ethics was the bulwark upon which was founded the Association, and that without it disintegration and collapse would follow. I cannot believe, nor do I want to believe, that a written code of morals is essential to the life of an organization made up of such men as are active workers in such an association. One of the best working societies in this country, and one which takes a more active part in public matters than any other, has already abandoned a code of ethics framed upon a liberal basis and is now working without any code at all." The *Western Medical Review* congratulates Dr. Bridges upon his courage in promulgating this sentiment, and declares he was only expressing the private views of a very large majority of the Society over which he was presiding.

The Playfair Dinner. — Upon the recent retirement of Dr. Playfair from the active staff of King's College Hospital he was made the recipient of a complimentary dinner, Lord Lister presiding. In his response to a toast drunk in his honor, he said: "When on leave of absence from India I noticed an advertisement in the medical journals for the post of assistant physician-accoucheur to this institution. My application was sent in, and I determined if elected to become an obstetrician. No more was thought of the matter until an intimation of my appointment was received, when I found myself confronted by two duties. One was to find out where the hospital was situated, and the other to learn something about obstetrics." Touching his now celebrated trial he departed from his determination never to mention it, especially in public, so far as to assure his hosts that all annoyance and distress connected therewith were more than counterbalanced by the warm symphathy he had received from the profession, his patients, and even from persons with whom he had little or no personal acquaintance. Among the manifestations from the latter was a letter from the late Mr. Gladstone commending the line of action he had taken.

CORRESPONDENCE.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

DOCTORS' DAY AT WIESBADEN — THE QUESTION OF WOMEN STUDYING MEDICINE AS GERMAN DOCTORS SEE IT — PROFESSORS LEYDEN AND GUSSEROW CONCERNING PREGNANCY WITH HEART DISEASE — AN ANATOMIC FOUNDATION FOR SOME PHASES OF PHYSIOLOGIC PSYCHOLOGY.

BERLIN, July 20, 1898.

UNDER the presidency of Sanitäts Rath Aub of Munich, "Doctors' Day," the occasion upon which the representatives of German medical societies meet to discuss subjects of interest to the doctors personally, in contradistinction to the meeting of societies to discuss scientific medicine, was held this year at Wiesbaden, June 28th and 29th. The relations of medical men to life-insurance companies were discussed, but from standpoints not of interest to American doctors generally. Somehow the impression one gathers from it is that the regulations now demanded by the physicians as regards fees, examinations, etc., are such as the liberal progressive policy of our great life-insurance companies introduced into the routine of business methods years ago.

A very interesting discussion, however, was that on the question of women studying medicine, which has been looked forward to with a great deal of interested anticipation by German medical men generally. The opening of the discussion had been referred to Professor Penzoldt of Erlangen, who evidently represented German medical opinion on the subject very well, since his conclusions in the shape of a thesis were adopted as the expression of the sentiments of the meeting by a large majority.

Professor Penzoldt is opposed to opening the doors to women for the study of medicine at present and states his reasons very forcibly. The demand for the privilege comes from two sources—the desire for equal rights and the wish to open up new vocations to women. As far as equal rights in education are concerned, he considers that what the world needs is not educated or half-educated women, but women healthy mentally and bodily, to fulfil the duties of wife and mother, which must remain for the vast majority of women the ideal and happiest vocation. He hopes that in this present women's movement this will not be lost sight of and future generations will have the precious privilege of knowing "*the genuine German woman.*" As to new vocations for women they are needed, but medicine must not be the first. It is extremely unsuitable, difficult and toilsome, and its rewards are small and slow for the majority of practitioners. Every one thinks he or she knows a little medicine, and thinks it will not be hard to learn more, but this is the veriest illusion. Women have shown themselves capable of pursuing university medical studies, but their success seems due to greater industry than men and to better memories, and very little can be hoped for from them as scientific investigators. They overdo the work. In practice they are much less successful than men and the few exceptions who have succeeded in making a successful career for themselves, are the pick of the sex who really prove the rule of woman's much less adaptability to practise medicine than men.

Medicine requires too much work, too long study, too great expense, too much preparatory education for woman. Other callings in the commercial and industrial worlds pay better, are easier, and are not so demanding. In the medical line, perhaps, the callings of dentist and apothecary may be suitable for them. As an outlet for their natural feelings, which is sometimes spoken of as a reason for their studying medicine, there is open to them the occupations of trained nurse and midwife. Much might be done to raise these callings to a higher plane of usefulness and lucrativeness, if a better class and better educated women would enter them, and especially is this true for midwives.

As to the objection sometimes raised, that women suffering from genital affections do not care to apply to a male physician until serious symptoms develop and then it is at times too late, or at least only recourse to the knife is possible, he said German doctors, as a rule, are too careful of the feelings of their patients for this to be true, and the doctors to whom such an objection would apply are fast disappearing. The real difficulty in this matter, as Professor Müller pointed out, is (1) that gynecologic affections begin so often with insidious symptoms; (2) that women are often careless of initial symptoms, and (3) that they fear to know the truth and dread the operation that may eventually be necessary. Professor Penzoldt's conclusions which by vote became the resolutions adopted by the meeting are: I. "If the privilege of practising medicine should be allowed to women under like conditions as to men (this not to include, however, the opening of schools to them), then under present circumstances there is no reason to think that there would be a rush to the profession. II. If, however, because of circumstances and conditions not foreseen at present, there should come such a rush, there would result therefrom (1) no special benefit to patients; (2) more harm than good to the women themselves; (3) least of all can any benefit be looked for from such a movement for the German universities or for scientific medicine; (4) the present position of the profession in the eyes of the public would certainly suffer from it; (5) no furtherance of the general good can be expected from it."

In addition to these resolutions the following from Dr. Reich of Breslau was adopted: "The preparatory education of women admitted to practise medicine must be the same as that of men and their requirements for examinations must be the same." There must be no question of women being allowed to neglect the study of general medicine to apply themselves to special branches. Notwithstanding the serious opposition, then, there is in the tone of the resolutions adopted something that indicates that it will not be long before women will be granted the privilege to practise in Germany as they have within the year been allowed in Austria and Hungary. I have stated before that the tendency in this direction is evident, and that the granting of the privilege is a matter of the near future. I see no reason to change such views in the face of the opposition so generally ex-

pressed at the meeting. The resolutions are the last protest of the conservatives against the inevitable and contain in themselves the acknowledgment of that fact.

At a recent meeting of the Charité Arzte (the Society of physicians and surgeons of the Charité Hospital) there was a renewal of the old-time discussion between Professors Leyden and Gusserow as to the question of valvular heart disease and pregnancy; that is to say, Professor Gusserow read a paper on the subject, and it was discussed by his own and Professor Leyden's assistants, Prosessor Leyden being unavoidably absent at the banquet celebrating the tenth anniversary of the Emperor's coronation. The same question was discussed four years ago and since then has been the subject of special attention on Professor Gusserow's part. He has had seventy pregnant patients with valvular lesions, but four cases proving fatal, forty-six of the women carrying their children to term. This is very different from the statistics of the clinicians who claim that fifty to sixty per cent. of these cases are fatal. Such statistics are evidently due to the fact that the internists see only the severest cases and their conclusions cannot form a rule for the practitioner.

As to abortion for failing compensation Professor Gusserow has found artificial termination of delivery much more dangerous than natural delivery and spontaneous abortion of much more favorable prognosis than that brought on. He thinks that Nature will in nearly every case bring about abortion herself if it is necessary. Meantime the judging of the indications for abortion is most difficult as states of disturbed compensation supervene at times that seem to be surely fatal in tendency yet recovery ensues, and badly disturbed compensation at the beginning of pregnancy may be followed by comparative well being later. In the discussion it was evident that Professor Leyden's opinion has been modified, and while still thinking the condition serious he does not judge quite so badly of it as before.

A recent meeting of the Berlin Physiological Society was taken up by a series of stereopticon demonstrations of Nissl preparations of brain cortex of various animals by Dr. Schlapp of Fort Madison, Iowa. Among them were some entire sections of the human brain in frontal and longitudinal directions, the first entire sections that have been prepared by this method. They give with low power excellent pictures of the various cell-layers of the cortex and a chance to compare parts of supposedly various function with each other. One fact becomes clear from this general view, that the opinion expressed by some anatomists, that the passage from cortex composed of a certain number of strata or cell-layers to one made up of more or less in number is always a gradual not an abrupt one, is not true. This abrupt transition can be found wherever motor passes into sensory cortex and seems to be especially marked where the optic region begins. A very definite stratum cell-layer exists in this region and the limits of this seem to form an anatomic basis for what so far has been known merely physiologically.

Henschen claimed that the optic region in human beings occurred only in the convolutions lying along the calcarine fissure. Manaco claims that not alone the internal cortex in the longitudinal fissure presides over sight, but that the external cortex of the posterior part of the occipital lobes is associated in this function. These new investigations seem to furnish a scientific basis for saying just what the limits of the optic region are. The characteristic layer cell formation in the cortex of what is known to be the optic region extends beyond the limits marked by Henschen, but never reaches the extent demanded by Monaco's theory. It ceases just where the internal cortex of the longitudinal fissure turns to become the external cortex. In monkeys whose optic region has been shown by Munk physiologically to exist also on the external cortex the characteristic cell-layers run over here. In other animals, as the *pteropus*, the flying-fox of South America, and the horse, it can be demonstrated that other sensory regions, especially those of hearing and smell, have a very definite cortical character in the peculiar arrangement of their cells, which enables the anatomist to very definitely point out their limits. This anatomic basis for physiologic functions of the brain cortex has long been sought in vain, and there are in the cellular arrangements of the cortical layers of the frontal and parietal lobes certain hints at an anatomic substantiation of some of Flechsig's speculations as to association centers that seem to make them of still further interest for physiologic psychology.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

PRECAUTIONS AGAINST YELLOW FEVER—ARMY APPOINTMENTS—PERSONAL NOTES—NEW HOSPITAL BUILDINGS—MEETING OF THE STATE BOARD OF HEALTH—ANOTHER "FAITH-CURE" DEATH—A DIPHTHERIA OUTBREAK—HEALTH STATISTICS.

PHILADELPHIA, July 27, 1898.

WHILE no alarm is felt by the authorities regarding the recent outbreak of yellow fever among the troops at the front, the local health board has determined to be prepared and with this view arrangements have been completed for a house-to-house inspection along the Delaware River front. Chief Nuisance Inspector Kennedy has a corps of twenty assistant-inspectors, and to this number have been added fifteen assistant medical inspectors who will have the matter in charge. Governor Hastings has also given the subject attention, and on Wednesday of last week held a conference with Dr. Benjamin A. Lee, Secretary of the State Board of Health. The Governor directed Dr. Lee to take every precaution necessary to prevent the introduction of yellow fever into any Pennsylvania port.

Dr. Edward Martin, recently surgeon to the Third Pennsylvania Regiment, has been promoted to brigade surgeon with the rank of Major. His place in the Third Regiment has been taken by Dr. Archibald G. Thomson, a son of Dr. William Thomson who was chief of the medical staff of the Army of the Potomac during the Civil War. Another army appointment is that of Dr. John A. McKenna who leaves this week for Falls Church,

Va., having received his commission as Acting-Assistant Surgeon, United States Army. Dr. J. C. Da Costa, Jr., who is also stationed at Camp Alger, was in Philadelphia a few days ago on a week's leave of absence. Dr. Joseph Sailer, formerly pathologist to St. Joseph's Hospital, and a member of the staff of the Pepper Laboratory of the University of Pennsylvania, has been commissioned Passed Assistant Surgeon in the Navy, and has been assigned to duty on board the "Arctic." John B. Scott, a third-year medical-student in the University of Pennsylvania and President of the Houston Club, died July 15th, having been home a few days from the auxiliary cruiser "St. Paul," on which he had served from the time she was commissioned by the Government.

At a recent meeting of the National Relief Commission held in Philadelphia, Dr. M. S. French, the secretary, read letters from every hospital in the city offering the use of their wards to the wounded of the Army and Navy. Letters in reply were read from Surgeon-Generals Sternberg of the Army and Van Reypen of the Navy in which they stated they would gladly avail themselves of this generous offer should occasion arise.

Among the names on the passenger-list of the Bremen steamer "Bremen," which sailed last week, were those of Dr. W. Esterly Ashton and his brother, Dr. Thomas G. Ashton. Dr. W. W. Watson, Professor Pfromm of the Medico-Chirurgical College, Drs. A. A. Apple, Paul Bartholow, and E. Sajous are at Atlantic City. Dr. J. Chester Morris is at his summer home near West Chester, while Dr. Joseph S. Neff is in the Adirondacks, Dr. Henry C. Chapman at Bar Harbor, and Dr. W. B. Atkinson at Asbury Park.

The Board of Trustees of the Medico-Chirurgical College has elected Dr. Robert S. Nones Dean of the Dental Department, and Drs. Walter H. Neall and James D. Price Adjunct Professors. A new ward to be known as the "Dulles Ward" is to be added to the Presbyterian Hospital. The plans call for a building two stories high, 40 x 48 feet, granite at the base with the upper part of brick, red stone, and terra cotta. The building is to be furnished throughout with steam heat and electric light. Another hospital building to be erected soon is the Ayre Memorial Building for the Pennsylvania Hospital. It will be similar to the Garrett Memorial Building, colonial in style, two stories high, and measuring 26 x 70 feet. It is to be used as a clinical laboratory in connection with the hospital, and the plans specify its completion January 1, 1899. The funds were bequeathed by the late Mrs. Josephine M. Ayre supplemented by a gift of $25,000 from her son, Frederick Ayre of New York.

The Pennsylvania State Board of Health met a few days ago at Swiftwater, Monroe County, in response to an invitation from Dr. Richard S. Slee, assistant bacteriologist of the Board. Dr. Benjamin S. Lee, secretary, read the report of the Schuylkill Investigation Committee, in which he said that at Plymouth Creek pipes conveying sewage were found emptying into the river, which presented the appearance of indigo-blue mixed with tar, and had an odor so bad as to compel the committee to turn away. From this point all the way to Bridgeport the water was thick with decaying vegetable matter and refuse thrown from the houses, the stench therefrom being almost unbearable. The farther up the river the committee went the worse became the conditions. At places no means whatever were taken to prevent household drainage and human excreta from entering the water, but apparently nothing was left undone to perfect arrangements for the conveyance of such matter to the river, all seeming to consider it a common receptacle for that which might cause disease if allowed to remain on land. At Pottstown, which for many years past has been considered one of the chief sources of pollution, privies have been erected on bridges or platforms over the water for the Hungarian population living along the banks. At Birdsboro nearly all the houses were found to drain directly into creeks which empty into the Schuylkill.

As a result of the report, of which the above is but a sample, the city of Philadelphia will unite with the State Board and other Boards of Health throughout the State in making a demand upon the Legislature for the passage of adequate laws for the protection of the purity of our streams. What is evidently so necessary in Pennsylvania suggests that similar sanitary reforms should be instituted in other States where investigation may reveal equally flagrant abuses.

After listening to the report the Board inspected the Pocono Biologic Laboratories, to which contracts for vaccine virus have been awarded by Surgeon-General Sternberg of the Army and the Philadelphia Board of Health. Dr. Lee said it afforded him much pleasure to say that Pennsylvania has two of the finest biologic laboratories in this country. The following gentlemen compose the board for next year: President, Dr. George G. Groff; secretary, Dr. Benjamin Lee, and Drs. John Fulton, James H. McClelland, Samuel T. Davis, and Richard Y. Cook.

The coroner's inquest in the case of an infant, aged fourteen months, who died last week of meningitis, revealed another death due to the negligence of "faith-curists." The child was taken ill on July 11th, but a physician was not called in until the 15th. Notwithstanding his warnings, the mother failed to give the child the medicine prescribed, and death occurred two days later. Certainly such negligence on a mother's part should be regarded as criminal, and a curb put upon the freedom from punishment which this cult enjoys.

An unusual number of deaths have occurred during July as a result of the excessive heat, and heat prostrations far exceed the record. Dr. J. Howard Taylor, Chief Medical Inspector of the local Board of Health, has been investigating the sudden increase in the number of cases of diphtheria, as shown by last week's report. He is of the opinion that no serious alarm need be felt, as the cases are of a mild type, and the number of cases is already on the wane. The most unusual feature of the outbreak is the fact that in one ward there were eleven cases, while in the same ward the week previous not a single case was reported. Eight cases of beri-beri were reported on board the German steamer "Steinbek," which arrived this week from Java.

TRANSACTIONS OF FOREIGN SOCIETIES.

Berlin.

IMPERMEABLE STRICTURE OF THE ESOPHAGUS FOLLOWING DIPHTHERIA — ENLARGEMENT OF THE PENIS FOLLOWING REMOVAL OF INGUINAL GLANDS —TREATMENT OF RECURRENT UTERINE CANCER— CAUTERIZATION AS A PREVENTIVE OF INFECTION —OVERFEEDING THE SOLE CAUSE OF CORPULENCE —PATHOLOGY OF BRONCHIAL ASTHMA—VALUE OF ORTHOFORM.

ROSENHEIM presented to the Medical Society, May 11th, a boy aged five years, who, after recovery from a severe attack of scarlet fever and diphtheria in his third year, suffered from a stricture of the esophagus twenty-two centimeters (nine inches) from his teeth. The caliber of this stricture decreased so much that even fluids could not be swallowed, and it was necessary to perform gastrostomy to save the boy's life. All attempts for some time to pass an instrument through the stricture, either from above or below through the fistula in his stomach, failed. At last a very fine sound was passed, and afterward a tent of laminaria, which by its swelling dilated the stricture so that the child could swallow fluid. Treatment was continued until by gradual dilatation the stricture was entirely cured.

EWALD mentioned two similar cases in which the stricture, though impermeable before the gastrostomy, had resolved of itself after the fistula in the stomach had been established. He explained this happy result by saying that the weight of the food in the stomach pulling on the esophagus gradually stretched and so dilated it that fluids and solid masses could pass the constriction. In both of the cases referred to the stricture followed ulceration, and was impermeable to the sound.

At the session of May 18th, MEYER presented a man with an enormously enlarged penis, the increase in the size of the organ following upon the double extirpation of the inguinal glands. It was due apparently to congestion, and there was not the slightest evidence of inflammation. The penis was of soft consistence. Meyer purposed to relieve the condition by a circumcision and resection of a wedge-shaped portion of the organ.

May 25th LANDAU showed a patient from whom he had removed per vaginam the uterus and adnexa for cancer. The growth recurred in a little less than three years, and he had performed an operation for the recurrence. The incision chosen was one beginning in the middle of the left labium majus, and extending backward, half encircling the rectum, and ending at the tip of the coccyx. This wound enabled the operator to remove the recurrent growths which had attached themselves to the bladder wall as well as to the small intestines. Through the vagina a gauze drain was inserted into the peritoneal cavity, and a tube was left in the perineal wound. The wounds were elsewhere sutured. The drains were removed on the fifth day, and the patient made a quick recovery. Landau advised the systematic inspection at regular intervals of all patients from whom the pelvic organs have been removed for carcinoma, as thereby recurrence will often be detected while there is still time to remove it. The incision above described is especially adapted to facilitate the removal of recurrences.

COHN read a paper in answer to the question, "How Far Does Cauterization of Aseptic Wounds Prevent an Infection with Diphtheria Bacilli or Pyogenic Streptococci?" From a long series of experiments with rabbits and guinea-pigs he concluded that cauterization with a stick of silver nitrate is far more powerful than all other caustic applications.

At the session of June 15th HIRSCHFELD spoke of the "Nutritive Needs of the Corpulent." Most authors have supposed that an excess of fat might be due either to a too great consumption of food or to a faulty constitution, which, without any overeating, could produce corpulence. Hirschfeld denies this latter statement, as his investigations have proved to him that corpulence is caused only by overconsumption of food. To settle the question he made observations to determine the amount of food required to keep normal individuals and those of unusual stoutness at an even weight. He found in them, except in so far as individuals differ one from another, no variations from a common law. One case was apparently an exception to this law. A prisoner who was upon a fixed diet made a rather rapid gain in weight of over fifty pounds. Investigation showed, however, that he had after several years incarceration obtained permission to receive sausage from home, which he ate in addition to the whole of the regular fare allowed him. To this overeating was due his increase in weight. The fact that so many women who are stout say that they are small eaters is explained by the writer on the ground that women are usually unwilling to confess to a large appetite.

At the Union for Internal Medicine, May 16th, Fränkel said that the variety of the anatomical conditions found in bronchial asthma indicate that there is not a single underlying process which is the same in all cases. In only four autopsies made upon patients who have died in an asthmatic attack have definite pathologic conditions been found. In one of these the finer bronchioles were filled with mucous clots, which, in some instances, took the form of Curschmann's spirals. The others had fibrinous clots, with the exception of one case, in which the bronchioles were blocked with the desquamated epithelium of an intense catarrh. Owing to the rarity of death in an attack of asthma of bronchial origin there is a sad lack of exact knowledge of the processes underlying the disease; but it may be taken for granted that a bronchiolitis with the formation of fibrinous clots must have been preceded by a marked destruction of the epithelial layer.

VON LEYDEN said that the scarcity of anatomic preparations which show the lesions of asthma is explained by the fact that as soon as an attack passes off the lungs of the patient are to all intents as sound as ever. For this reason, in making many autopsies upon asthmatic subjects, he had never found in a single instance anything in the lungs to explain the occurrence of the attacks. Often, indeed, when asthmatic patients are suffering from some more serious trouble which may cause death, the attacks of asthma disappear. The diag-

nosis during life is made without difficulty by the characteristic crystals which are found in the sputum. In a typical case, especially in young people, the patient coughs and wheezes, but brings up nothing at the height of the attack. When this has passed over a little he raises a stringy mucus, which is seen under the microscope to contain a network of fine fibrinous threads, the meshes of which contain the characteristic Leyden's crystals, and numbers of large epithelial cells. Later the fibrinous masses are set free and epithelial clumps are found in great abundance. In all probability these fibrinous plugs are formed by the coagulation of a serous exudate in the finest bronchioles or even in the alveoli, and as they are separated they bring away with them the epithelial lining of the bronchioles. If the loosening proceeds further mucous and mucopurulent balls appear in the sputum, the fibrinous plugs and crystals disappear. In chronic cases the bronchioles do not become entirely free, but there remains in the finest bronchioles a certain amount of mucous or epithelial matter, which produces emphysema. Still in some chronic cases the restoration to the normal after an attack is so perfect that nothing at autopsy shows that there has been any asthma. This is the more encouraging clinically, as showing that bronchial asthma, even in its severe form, is not incurable, and that the patients suffer more from the complications which are apt to appear in advanced age, than from the asthma itself. This is particularly true of arteriosclerosis. Bronchial asthma may be spoken of as fibrinous broncholitis, but though it has much in common with fibrinous bronchitis, it is not the same thing, for fibrinous bronchitis may exist without asthma. It may also come from an acute catarrh, but only in individuals who are predisposed to asthmatic attacks.

Eosinophile cells are seen in great numbers in the sputum in almost every attack of asthma. The most rational explanation of this fact is that the serum which exudes in the alveoli and in the small bronchi, and which later forms the coagulations and the crystals, has a chemotactic action upon the eosinophilic cells of the blood, drawing them thither in great numbers. Attempts to make of asthma an infectious process have failed. That infection is not present is shown by the absolute lack of suppuration in the fresh attacks. The micro-organisms which have been described in this connection have their origin doubtless in the larger bronchi.

MOSSE reported the "Results of Six Month's Experimentation with Orthoform." This powder was used by insufflation in painful affections of the upper air-passages, whether tubercular or due to acute poisoning, or of an infectious nature, such as angina or diphtheria. In all these cases the orthoform showed itself possessed of anesthetic power, lasting some hours more or less. Internally it was given either as a powder or in solution in doses of 1 to 1.5 grams (15 to 22 grains) for ulceration of the stomach. The powder sometimes provoked nausea, and the solution is therefore recommended. No other objectionable symptom was developed, but at times it appeared as if the patient grew accustomed to the drug, which thereby lost some of its efficiency.

HERZFELD found orthoform of much use in syphilitic and tuberculous ulcers of the throat. The effect lasted for some hours, in rare cases for a whole day. The difference in the duration of the relief from pain might be due to the varying amount of secretion present. It is purely a local anesthetic, and has no effect on the healing process.

VON LEYDEN had found orthoform of great value, and looked upon it as the best substitute for cocain, which it surpasses in being free from any general constitutional effect. It can, therefore, be prescribed without the fear of injury which sometimes follows the administration of cocain.

FRAENKEL called attention to the fact that orthoform has no effect upon the sound mucous membrane or skin, and in this respect cannot altogether take the place of cocain.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, Held May 18, 1898.

THE President, L. DUNCAN BULKLEY, M.D., in the Chair.

ASCENDING OPTIC NEURITIS OF PROBABLE SYPHILITIC ORIGIN.

DR. ROBERT H. GREENE: I would be very glad to have any suggestion made as to the treatment to be employed in the following case. The patient, a man, came under my care two years ago suffering from tertiary syphilis. I put him through a most vigorous course of inunctions and also gave him mercury and iodid of potash internally and tonics to improve the general condition. He did well under this treatment until six months ago when he began to complain of poor vision in the left eye. He was examined by Dr. Kalish, who came to the conclusion that the man was suffering either from optic neuritis or commencing atrophy of the optic nerve. Dr. Collins also saw the patient and expressed the same opinion. At the latter's suggestion I gave the patient strychnin until its physiologic effect was obtained, and also hypodermatic injections of mercury, but without effect. Finally I employed fumigations of calomel and cinnabar and a Charcot spinal douche. His general condition improved and the sight of the left eye became somewhat better. The latter improvement was only temporary, however, and the right eye has now become affected. During the daytime, especially in the glare of the sun, he is almost totally blind. He sees better at night, but he complains of a burning sensation in his eyes. In other respects he seems perfectly well and feels better than he has for years. This is a very meager history from which to make a diagnosis, but if any of the members can express an opinion as to the pathologic condition present I will be very glad. The diagnosis I think lies between optic neuritis, hemorrhage, and gumma.

DR. ROBERT MILBANK: I would like to ask Dr. Greene as to the condition of the pupil of the affected eye

Last November I presented a case before this society in which there was dilatation of the pupil of one eye which had come on suddenly three years previously in a patient who had suffered from syphilis. Under pilocarpin or eserin vision in that eye was as good as that of the other, but as soon as the effect of the drug wore off the pupil again enlarged. It was suggested that he be kept under mercurial treatment, although he showed no other symptoms of syphilis at the time, and ever since he has been taking an eighth of a grain of biniodid of mercury three times a day. The condition of the pupil has not changed however.

DR. ROBERT A. MURRAY: Experience has taught me that these patients improve up to a certain point, reaching a pretty fair state of nutrition, but they progress no further under treatment. The iodid seems to lose its power and some nerve manifestation appears. Occasionally, pilocarpin administered for a little while will result in increasing the effect of the other drugs. I have also seen good results follow the use of conium, given in combination with the iodid. Arsenic in the form of Fowler's solution also aids mercury in its action. If the patient becomes stout under treatment, as is apt to be the case, we should watch the kidneys carefully, for trouble in these organs is very likely to develop. I have also noticed that when the nervous system becomes involved the effect of remedies is less than in patients who do not have this complication. Their condition will remain stationary for a long time and it is almost impossible to obtain any effect from medication.

DR. S. H. DESSAU: Following out the same line of thought suggested by Dr. Murray in regard to the action of the iodid of potassium and the mixed treatment in syphilis, especially in the tertiary stage, I would like to call attention to the use of coca as an adjuvant. I have seen it employed with very remarkable effect in cases in which the patients have been under treatment for years previously without benefit. In one case in particular in which all the manifestations of the disease were present the effect was marvelous. When the patient was first seen there was extensive sloughing of the calf of the leg. He afterward had an eruption of pityriasis rubra universalis, at least a hatful of scales being desquamated daily. Nervous manifestations subsequently appeared, with paralysis of the right deltoid muscle, and finally the patient developed elephantiasis of one leg, and also brain symptoms. At this time he was taking massive doses of iodid of potassium without benefit. As he was very anemic he was also given iron, and, finally, I gave him coca, having read somewhere that this drug is useful in such cases. After he had taken the coca for a week a wonderful change took place, and the elephantiasis disappeared in a short time. Since then I have looked up the literature to see if mention has been made of this remedy, and I find that it is referred to in an Edinburgh journal and also in the edition of Bumstead's work edited by Dr. Taylor.

DR. JOSEPH COLLINS: I examined the patient referred to by Dr. Greene and found the man suffering from well-marked atrophy of the optic nerve of the left eye and a beginning atrophy of the nerve of the left eye. There were no other nervous manifestations. The condition is not especially rare and is in no wise remarkable. Such cases are described in the books as one of the cranial nerve manifestations of syphilis. It is impossible to say whether the lesion is a syphilitic degeneration of the nuclei of the optic nerve of whether it is an infiltration of the sheath. We all know that syphilis has a marked predilection for the cranial nerves, and the second pair is unfortunately often involved. Sometimes it affects the nuclei, sometimes the gummatous formation encroaches on the nerve trunk. A certain proportion of syphilitics become blind from ascending atrophy, and the case in question is an instance of this. I was asked to see the patient largely because it was desired to exclude tabes and beginning general paresis. It was not difficult to do this because there were no symptoms of tabes, no Argyll Robertson pupil, no change in the knee-jerks, no disturbance of sensation, and none of the physical and mental manifestations of the latter disease. By a process of exclusion and from ophthalmoscopic examination the diagnosis of the ascending optic neuritis was made. It was considered that this was a syphilitic lesion, and I advised that the patient be given hypodermatic injections of mercury alternated with hypodermatic injections of strychnin. It is very sad to watch these patients go on to complete blindness but there seems to be no way to prevent it. I have no doubt that the President has seen such cases in the institutions with which he is connected, in the reports of which they unfortunately often figure.

DR. MURRAY: In regard to pilocarpin in syphilitic diseases of the eye, especially those due to gummata, in which it is said that in the beginning the trouble is not due to atrophy of the nerve but to an effusion around the sheath, pilocarpin administered until its constitutional effects are produced will result in an astonishingly rapid absorption effect. Should any secondary effect be noticed, this can be contra-acted by atropin or strychnin. The pilocarpin acts by stimulating the glands of the skin, an effect similar to that which follows hot baths. Large quantities of the iodid should also be given. It is logical to conclude that anything which will stimulate the glands will make the remedies used more potent.

DR. RICHARD KALISH: I saw this patient of Dr. Greene's in August, 1897. There was some hyperopia with irregular astigmatism and quite a number of floating bodies in the vitreous. The nerve head was bluish in color, and slightly excavated in the center. The central artery was reduced in size and the veins dilated. There was no evidence of the existence of retinitis or of choroiditis. The perimeter showed a contraction of the field of vision on the nasal side. I agreed with Dr. Greene that the probable cause was syphilis, and that the patient should be treated on that basis.

In December I saw the patient again and found his vision to be somewhat improved. The floating bodies in the vitreous were less in number, the nerve was paler in color, and the arteries and veins reduced in size. There was an improvement in the field of vision, it being about normal. I could see no reason for changing my diagnosis and advised a continuance of the treatment.

THE PRESIDENT: The mention of conium reminds me that this is a remedy commonly employed by me. I have found that the extract has more effect than conium in tablet form.

DR. J. HENRY FRUITNIGHT then read the paper of the evening, entitled

HEREDITARY INFANTILE SYPHILIS. (See page 129.)

DISCUSSION.

DR. WILLIAM STEVENS: The author has handled the subject in a most thorough manner. I recall a case of a child about five years of age, whose father had suffered from syphilis. I had lost sight of the family after I attended the mother when the child was born. I found the child pigeon-breasted and very feeble. I ordered iodid of potassium and mercury, the latter in the form of calomel, $\frac{1}{10}$ of a grain several times a day, and also cod-liver oil. The child improved very much, gained in weight, and a great deal of the apparent malformation of the chest disappeared within three weeks.

DR. MURRAY: The subject is an extremely interesting one to us all and we should thank the author for bringing it before us. The paper is especially valuable for the reason that it informs us of the signs by which we can determine the existence of hereditary syphilis. It is absolutely necessary that we be able to do this because of the impossibility of obtaining a reliable history from the parents. It is proverbial that persons with syphilis or gonorrhea are liars. It is useless to question the father or mother in these cases for they will only mislead one. We must be able to recognize the signs of the disease. An important point to remember is this: When a miscarriage occurs, make careful observations in order to find out, if possible, what caused the death of the fetus. Or, if this cannot be done without arousing the woman's suspicions, examine the epiphyses of the long bones, also the hair. I have already reported two cases in which I was able to make the diagnosis in this way, and by treatment vigorously employed have been able in subsequent pregnancies to carry the patients to full term and deliver them of living children. It is extremely difficult to make a diagnosis of hereditary syphilis in young children in cases in which the mother has been delivered by some other physician. The history obtainable from the parents is always too meager and unreliable to tell us anything. The existence of the disease can usually be determined by the presence of snuffles in the child, although it must not be lost sight of that this symptom may be due simply to a cold.

In regard to the treatment of the syphilitic pregnant woman, I believe there is nothing better than inunctions of mercury. If the drug is given by mouth it often upsets the stomach and adds to the nausea. Another reason why inunction acts well is because when this method is employed the patient is obliged to bathe frequently and the result is that the skin is kept active. Then, too, mercury is much better for pregnant women than iodid of potassium. For infants I employ mercurial inunction immediately after birth, and also inunctions of cod-liver oil to relieve the inanition and marasmus. In the very bad cases there is nothing to be done; the children always die. The main point is to make the diagnosis in the mother, to institute treatment at once, and to carry it on to the very day of confinement. If the treatment is not kept up late the child may die at the last moment or during labor, for, if the woman has never before given birth to a full-term child she will probably have a difficult labor, and the child will not stand much pressure with forceps. The latter point is an important one for obstetricians to bear in mind. Hydrocephalus is also common in syphilitic children, and I have seen several cases in which there was hydroperitonitis.

DR. KALISH: In regard to the point made by the last speaker, *i. e.*, that the parents of this class of patients are liars, I would like to narrate an experience which strongly bears this out. Some years ago in the late spring a nursing woman was brought to me suffering from neuroretinitis. I happened to know that her husband had had syphilis some years previously and had declined treatment. I ordered that the baby be weaned and put the woman upon appropriate treatment which resulted in curing the retinitis. While she was under my care she brought the child to me. It had the typical symptoms and there could be no doubt that it was suffering from hereditary syphilis. The father insisted that I treat the child as he did not want the cause of its illness to become known. I consented to take charge of the case and ordered small doses of gray powder and cod-liver oil inunctions. The eruption disappeared in a marvelously short time and the child improved in every way. I then left town for the summer and turned the case over to a colleague with instructions to continue the treatment. For some reason unknown to me this physician was not acceptable to the parents and they took the child to another medical man without informing him as to the history of the case. The child was treated for marasmus and died within six weeks. When I asked the father why he had not told the physician the nature of the trouble from which the child was suffering, he replied that he thought it was the doctor's business and not his to find out what ailed the child.

DR. GREENE: There is only one point in the author's exceedingly valuable paper upon which I am obliged to disagree, and that is in regard to the existence of scars around the child's mouth being a positive diagnostic sign of syphilis. There is no doubt that in the majority of cases these scars are due to syphilis, but such is not the case in every instance. A patient in whom these scars were present in a marked degree was recently shown before the Genito-Urinary and Dermatological Society, but there were no other evidences of syphilis in the child and none in the parents. The scars were apparently due to some trophic nerve disturbance, causing atrophic changes in the skin which had taken place during fetal life.

I am quite in accord with the author in regard to treatment. I would suggest, however, that the tannate of mercury is an agreeable form in which to administer this drug to children. It can be given dissolved in milk. Iodid of potassium when given in infantile syphilis gives good results in the same class of patients as it does in

adults., *i. e.*, those who have syphilis of the deeper tissues of the body. In such cases my experience has shown that large doses can be given. Small doses may be given at first and gradually increased. I once gave to a child four years of age from 200 to 300 grains of the iodid during a period of several months, with exceedingly good results. The prognosis of the disease in children is very much like that in adults. If the child is born with syphilis and the deeper structures of the body are attacked the outlook is bad. If the skin and mucous membrane alone are involved the prognosis is more hopeful. My experience leads me to believe that in a large proportion of cases the disease is acquired soon after birth and is not congenital. I have seen four or five cases of chancre of the tonsil in young babies.

DR. MILBANK: The author told us that he did not propose to treat the subject of hereditary infantile syphilis in an exhaustive manner, and this accounts for the fact that lesions of the osseous structures are barely touched upon in the paper. These are most important for they usually develop early and are, therefore, valuable diagnostic signs. The longer the interval between the infection of the parent and the appearance of syphilitic manifestations in the child, the less of an inflammatory nature are the bone lesions. We often find osseous lesions of a low grade of inflammation in young children, and in some cases it is very difficult to make the diagnosis. In two cases which came under my observation this was determined by the result of antisyphilitic treatment.

I am compelled to disagree with the author in his statement in regard to the diagnostic significance of "Hutchinson teeth." There are two varieties of "Hutchinson teeth"—the small "peg" teeth and the notched teeth. The former are not pathognomonic of syphilis, but I never saw a case in which the latter were present in which syphilis could be positively excluded. The most frequent lesion of early syphilis is the fissures of the anus which are positively pathognomonic. In regard to treatment, I use inunctions in preference to anything else, although I occasionally employ gray powder.

DR. MURRAY: Some years ago I made the assertion that when a woman contracts syphilis during a pregnancy the child is seldom born alive. She will usually miscarry. Snuffles is one of the earliest symptoms of infantile syphilis. It interferes with the nutrition of the child, and causes a great deal of restlessness which robs the mother of her rest. I have found that this symptom can be relieved by bromid of potassium, ¼- to ½-grain every two hours.

DR. DESSAU: The paper deals largely with the question of diagnosis, and there are a few remarks I would like to make upon this point. My experience has led me to think that we cannot depend upon any one sign or symptom in making the diagnosis of infantile syphilis. Notched teeth have been mentioned as pathognomonic. I know for a fact that the younger men are very apt to be led to make a diagnosis of syphilis from this one symptom. This is a great mistake. The notched teeth of hereditary syphilis are the second teeth. If the first teeth are notched, the cause is rickets. When the permanent teeth are notched, some other lesion of syphilis is almost invariably present.

As to the eruption, I do not think that even an expert is justified in making a diagnosis of infantile syphilis from the eruption alone. There must be a multiplicity of lesions in order that the disease may be identified. Dr. Murray has mentioned a manifestation which is rare but which I have seen, *viz.*, peritonitis; but I do not think that any one would be willing to make a diagnosis of syphilis in a new-born babe because it had peritonitis. I was taught that an eruption on the palms of the hands and soles of the feet was diagnostic of hereditary syphilis, but I have found that this alone is not more reliable than any other single lesion for I have seen it in patients who were not syphilitic. It is important to recognize the fact that the diagnosis must depend upon the clinical picture which the patient presents. In regard to treatment, mention has been made of many remedies, but I have failed to see a case in which any other drug than mercury was necessary. I use inunctions only and have never seen a child who did not respond to this treatment unless its condition was extreme. I would never administer mercury internally to a new-born infant.

I recently saw in consultation a very interesting case of acquired syphilis in a young child. It was one of five who had contracted the disease from its mother who had a chancre of the cheek. These cases have elsewhere been reported as "an epidemic of syphilis." The child in question was ten months old and at the time I was called was supposed to be suffering from laryngeal stenosis. There was no difficulty of respiration, however. The child was intensely anemic and had a characteristic macular eruption. There was extensive swelling and infiltration of the tonsil and pharyngeal wall, which were superficially ulcerated. There was also infiltration of the lymphatics of the neck. Suppuration and evacuation occurred subsequently and the urgent symptoms were relieved. There was no rise of temperature. The case was evidently one of post-pharyngeal abscess of syphilitic origin.

DR. A. M. JACOBUS: My experience in treating hereditary syphilis has been so limited that it is not worth mentioning. As to gray powder, I believe it to be more efficient and better borne than any other mercurial, calomel ranking second. I am surprised at the large amount or daily dose recommended by the author for young children, for, while these are my favorite remedies in the treatment of syphilis, I have never found it necessary to give more than six or eight 1-grain gray powder tablets, or from four to six ¼-grain tablets of calomel, per day even to adults. In this connection I desire to report a case in order to create discussion as to the causal relationship, if any, of syphilis in the mother and anencephalus in the fetus, complicated by hydramnion.

Mrs. L., aged twenty-four years, married in 1894, gave birth to her first baby in July, 1895, and through infection, believed to have been contracted from a water-closet seat used by a servant who was later found to be suffering from syphilis, developed a chancre on the left

labium majus in December, 1895. The initial lesion was not recognized until later. An attack of measles masked the early symptoms, and it was not until a well-marked squamous syphilide of the palms of both hands broke out in March, 1896, that the diagnosis was made. This was confirmed by Dr. A. R. Robinson, and the patient put upon specific treatment. Somewhat after the Hutchinson method, she was given four to six ¼-grain calomel tablet triturates per day, according to their effect, alternating every two to three weeks with 1-grain tablet triturates of gray powder six to eight times a day. The eruption and other symptoms of syphilis rapidly disappeared under the treatment. The gray powder seemed to cause less flow of saliva and less frequent action of the bowels. The young woman again become pregnant in September, 1896, but aborted in November, probably as a result of the syphilis. In May, 1897, she became pregnant for the third time after having been taking the mercurials some fourteen months. The patient was advised to continue her medicine daily, but during the summer, partly from carelessness and partly because she felt so well, she omitted the mercurials for some two or three months, until I saw her again after her return to the city, when the desirability of further treatment until confinement was brought to her attention and insisted upon. After the fifth month of pregnancy the mother suffered greatly from the violent movements of the fetus which increased in force as gestation progressed and could be seen across the room as the abdomen was struck from within. During the last few months of pregnancy the abdomen became very large and tense, and this, together with the violent movements led her to believe that there were twins in utero. I made a careful examination at the eighth month, but the tension was very great, and, although I was puzzled at not finding the head either high or low, I concluded that there was but a single fetus with dropsy of the amnion.

Labor set in late on February 13, 1898, with a transverse presentation, and early on the 14th, not being able to fix the head at the pelvic brim, I ruptured the membranes, discovered that there was a malformation of the head, and shortly after delivered the child which proved to be a typical case of anencephalus. The child did not move after the body became engaged; it was perfect except for the entire absence of the skull and brain, there being nothing but a flat, hairy scalp, and a macerated or raw fleshy spot about two inches in diameter in the center at the foramen magnum. The amniotic fluid was not measured, but probably amounted to eight or ten quarts and had a peculiar odor like that in cases in which a fetus has been dead in utero for a week or two. The patient was up and about at the end of the second week but developed a slight phlebitis or lymphangitis in the left femoral region during the third week which caused a return to bed for about ten days, after which the puffy extremity and the indurated condition under Poupart's ligament slowly disappeared in the course of six months.

The question is whether the syphilitic taint in the mother caused the malformation of the fetus and the polyhydramnion. The transverse presentation was of course due to the two latter conditions.

THE PRESIDENT: There is one remedy which has not been mentioned in the treatment of hereditary infantile syphilis, *viz.*, the syrup of the iodid of iron in large doses. The Hutchinson treatment (the precipitates with gray powder tablets, and calomel tablets) is simply ideal. It is extremely important to keep the mother under mercurial treatment until the child is born.

DR. FRUITNIGHT, in closing: Much has been said which I had in mind, but, as I said before, the paper was not intended to cover the whole ground. In regard to the radiating scars at the angles of the mouth, it seems to me that in most cases these are diagnostic. If these exist with no other symptoms, this would prove to me—what I have always thought very probable—that syphilis had existed in the mother while the child was in utero and the disease had been checked by appropriate treatment. I touched upon the bone lesions which have been referred to by one of the speakers. I do not consider the "Hutchinson teeth" as absolutely pathognomonic; nor do I think that the diagnosis of hereditary syphilis should be made from one symptom alone. There seems to be some confusion as to the terms congenital and early syphilis. The former applies only to those cases in which the disease is present when the child is born; the latter to those in which the disease is acquired, as from a wet-nurse, after birth. If a woman who is suspected to be syphilitic has been nursing her child, the latter should be placed under treatment at once to counteract the bad effect of the milk. In regard to Dr. Jacobus' case, it has been proved that syphilitic infection is apt to produce hydramnion and hydrocephalus in the offspring.

REVIEWS.

A LABORATORY GUIDE IN PHYSIOLOGY. By WINFIELD S. HALL, PH.D., M.D., Professor of Physiology, Northwestern University Medical School, Chicago. With Appendices on Organization and Equipment. Two colored plates and sixty illustrations. Chicago: Chicago Medical Book Co., 1897.

TO students and laboratory workers in practical physiology, this little book is a valuable aid, but a fair knowledge of mathematics, physics, and anatomy is required as a working basis. The inductive methods of study are used. "The student is given the technic and, through a series of questions, he is guided in his observations. He is not, however, told what he is expected to observe, nor is he told what his conclusions are expected to be." In a well-equipped laboratory with sufficient trained instructors, this general plan will usually succeed and be most satisfactory. Without the above-named assistance, however, the book is occasionally too vague and concise in statement to be of great practical value.

Under the heading of "General Physiology," the methods of observing ciliary motion and the various effects of stimulation of muscle and nerve tissue are described. The subjects presented in Part on II. "Special Physiology"

are: the circulation, respiration, digestion, and absorption, vision, physiological hematology, and an introduction to pharmacology. Other subjects, excretion, animal heat, the voice, hearing, and the nervous system, are promised in a future edition. The appendices contain a description of laboratory appliances and instruments, fully illustrated, and a table giving their cost.

The book has been written with a distinct purpose, and, although its range of application is limited, its usefulness is evident.

THE AMERICAN YEAR-BOOK OF MEDICINE AND SURGERY. Being a Yearly Digest of Scientfic Progress and Authoritative Opinion in All Branches of Medicine and Surgery, drawn from Journals, Monographs, and Text-Books of the Leading American and Foreign Authors and Investigators. Collected and arranged, with critical editorial comments, by twenty-seven contributors, under the general editorial charge of GEORGE M. GOULD, M.D. Illustrated. Pp. 1077. Philadelphia: W. B. Saunders, 1898.

WHEN one considers the enormous yearly strides made in the medical sciences, the vast amount of original contributions to medical literature and the verification of new facts and discoveries some notion may be obtained of the stupendous work involved in the publication of a *Year-Book*, such as the one under consideration.

The general arrangement of the book is similar to that of the two preceding volumes, and the editorial staff remains practically the same. We note the resignation of Dr. Henry Leffmann, who formerly edited the Chapter on Medical Jurisprudence, Hygiene, and Clinical Chemistry, and the division of this chapter into three distinct departments with three new writers, *viz.*, Legal Medicine, by Wyatt Johnston; Public Hygiene and Preventive Medicine, by Samuel W. Abbott, and Physiologic Chemistry, by John J. Abel.

To review the articles in a work of this kind *seriatim*, would be to review the current medical literature of the year. Suffice it to say, therefore, that the work is a most faithful portrayal of all the advances in medicine, exceptionally well edited and arranged, and throughout clear and concise in statement. A simple glance at the full and excellent index demonstrates that it is a veritable encyclopedia. The previous volumes have heretofore occupied the highest plane among books of this kind, and we prophesy for the present one a continuance of this popularity.

TRANSACTIONS OF THE BRITISH ORTHOPEDIC SOCIETY. Vol. II., 1896. Published by the Society. London: John Bale, Sons & Danielsson, 1897.

THIS is a small pamphlet containing eighteen communications pertaining to this special department of surgery. "Congenital Dislocation" is represented by four papers contributed by W. Thomas, N. Smith, Tubby, and Keetley, each of whom offers a different plan of treatment for this affection. The bloodless method of Lorenz receives but scant attention. The Society has under consideration a plan to make a collective investigation as to the results following the various methods employed in treating this malady. An interesting article is that on recrudescent rickets by R. Jones, a subject which has received renewed consideration in connection with coxa vera, which affection is not mentioned in the discussion of the paper. In a discussion on "The Early Diagnosis of Affections of the Spinal Column," W. Thomas calls the attention of the Society to a new diagnostic element early in the development of scoliosis, a clonus of the erector spinæ produced by pressing sharply on one shoulder and then holding it firmly. The remainder of the articles are commonplace.

THERAPEUTIC HINTS.

Removal of Freckles.—1. Apply the following lotion to the face morning and evening:

℞ Zinci sulphocarbolat . . . . . ʒ i
Glycerini . . . . . ℥ ii.
M. Sig. External use.

2. Cover the freckles every other day with the following ointment:

℞ Hydrarg. ammoniat. } aa . . . ʒ i
Bismuth subnitrat. }
Glycerit. amyl. . . . . ℥ ss.
M. Ft. ungt. Sig. External use.—*Tonvenaint.*

Local Application in Gout.—

℞ Potassii iodi } aa . . ʒ iv
Liniment saponis }
Ol. cajaputi } aa . . . ʒ ss
Ol. cari }
Spiritus rect. . . q. s. ad. ℥ vii.
M. Sig. Apply on lint and cover with a protective.

For Syphititic Arthritis.—In cases in which the acute local pain and sensitiveness preclude mercurial inunctions or subcutaneous injections it is recommended to begin with internal mixed treatment as follows:

℞ Hydrarg. iodi rubri . . gr. iss
Potassii iodi . . . gr. lxxx
Sherry wine . . . ʒ v
Aquæ. . . . q. s. ad. ℥ vi.
M. Sig. Two tablespoonfuls a day.

For Psoriasis.—The following internal treatment is recommended by Brory in conjunction with external applications:

℞ Sodii arseniat. . . . . gr. $\frac{1}{10}$
Sodii salicylat. . . . . gr. xlv
Sodii bicarb. . . . . ʒ ii
Syr. saponariæ . . . . ℥ iv
Tinct. gentian. comp. } aa . . ℥ ii.
Syr. simplicis }
M. Sig. One tablespoonful three times a day at mealtime.

For Ivy Poisoning.—Keep affected parts wet with freshly made lime-water. Give the following mixture internally:

℞ Ext. tritici fl. . . . . ʒ iv
Spts. etheris nitrosi } aa . . . ℥ i.
Syr. limonis }
M. Sig. One teaspoonful four times a day.

HEMORRHOIDS AND THEIR TREATMENT.[1]

BY JOHN F. ERDMANN, M.D.,

OF NEW YORK;

PROFESSOR OF PRACTICAL ANATOMY AT BELLEVUE HOSPITAL MEDICAL COLLEGE; ATTENDING SURGEON TO GOUVERNEUR, ST. MARK'S, AND CHILDREN'S (ST. JOHN'S GUILD) HOSPITALS.

FROM the writer's standpoint, hemorrhoids are distinctly a surgical affection, and as such they will be treated in this paper, although the palliative treatment will receive its share of consideration. The close association of hemorrhoids with the genitals makes the discussion doubly interesting to the specialist and the general practitioner. It is not the object of the writer to enter into a prolonged discussion of the causes, nor is the anatomy to be considered in detail, but he trusts that a short description of the pile-bearing area and a few words relative to the causes of hemorrhoids will not be amiss.

The pile-bearing area is but about two and one-half inches in length, beginning at the anal margin, richly supplied with branches from the sacral plexus, and abundantly furnished with arterial and venous channels. It is interesting at this point to note the descriptions given to the end filaments of the veins. They are variously stated as ending in the so-called derivative circulation to that of small sacculations or dilatations, and it is this latter description that is most frequently accepted. To this accepted venous termination the entire hemorrhoidal theory is ascribed. The arteries supplying the pile-bearing area assume a course parallel to the long axis of the bowel instead of transversely, as in the remainder of the intestinal tract. The mucous membrane in this region is peculiarily arranged, particularly so at the lowermost portion of the area. Here the membrane is thrown into folds or columns, forming sinuses known as the columns and sinuses of Morgagni. These folds and columns, with their intervening pouches, frequently, especially so when inflamed or congested, are taken for piles, and it is in this structure that the quack finds his rich reward. These pouches can be everted in all cases, when the bowel is in a normal state, by placing the hands on the buttocks, the patient then bearing down, and as he does so traction being made on each buttock with the fingers. They will then be seen as folds of mucous membrane, and resemble very much in their general appearance small semilunar valves with their concavities upward. A probe can be passed downward behind the membranous-like flap for a distance varying from one-sixth to one-half an inch, and owing to this peculiarity they are frequently but wrongly called fistulæ.

One who sees many cases of these protrusions is astounded in taking the histories at the percentage of patients who ascribe their disease to attacks of diarrhea, although almost all accepted authors lay great stress on the influence of constipation as the causative factor. It cannot be gainsaid that a relative condition exists between varicose veins and hemorrhoids, as in a great many cases of hemorrhoids other varicosities are found. Naturally, with a predisposition to varicosities in the veins at other parts of the body, a very slight exciting cause is necessary to produce the evil. Some of these causes are obstruction to the venous return, as produced by constipation; intrapelvic tumors; retrodisplacements of the uterus; pelvic exudates; atonic condition of the musculature of the rectum and sigmoid; rigidity or stricture at the anus; expulsive efforts as noted during attacks of diarrhea and in the expulsive efforts when the outflow from the bladder is for any reason involved, as in cases of stone, stricture of the urethra, enlarged prostate, cystitis, etc. Alcohol, sexual excesses, masturbation, and even unsatisfied sexual desire are said to be predisposing factors. High living and sedentary habits are also contributing causes. Recently the writer operated in a case which was said to have had its origin in physical exercise. The patient in this case was a prominent amateur athlete, who said that his condition was due to overtraining.

In the general symptomatology the cardinal objective sign is the protrusion of a mass, either constant, or only seen following the act of defecation. This protrusion varies in size from that of a pea to one that practically surrounds the anal margin, and is from a quarter of an inch to an inch or more in length. Hemorrhage, as a sign, is as likely to accompany irritable ulcers, the so-called fissures, fistulæ, malignant diseases, and polypi, as it is to accompany hemorrhoids of the bleeding or capillary variety. Subjectively, the patient is apt to complain of pain at the time of or immediately after the act of defeca-

[1] Read before the Northwestern Medical and Surgical Society.

tion, discomfort, and a sense of an imperfectly emptied bowel, and of tenesmus, which is frequently due to the sphincter grasping the protruded mass. Pain is frequently present in the lumbar region, which may even extend to the thighs and legs. In addition to the symptoms directly referable to the anal region, there is frequently a chain of nervous symptoms of which mental depression, probably due to the fear of the trouble becoming malignant, irritability, fear of some impending disaster, and sexual impairment predominate.

Hemorrhoids, as far as the general practitioner is concerned, may be divided into two great classes, the external and internal. The external ones are those which arise from the tissues outside the external sphincter, while the internal variety consists of those which arise from the lower portion of the rectum, and are seen only when protruded after a movement of the bowels, or protruded as a result of some physical effort, or can be seen upon instrumentation with the speculum or the Kelly proctoscope. The external are subdivided into three varieties: the thrombotic, the cutaneous, and the venous. The latter variety is liable to become edematous, and is then called by some the edematous pile. The thrombotic variety is usually found in the mucocutaneous margin surrounding the anus. They are due, as a rule, to rupture of one of the veins about the anus, occurring as the result of straining during the act of defecation. The pile is hard, very painful, sensitive to the touch, bluish in appearance, and contains clotted blood. The second variety, the cutaneous, is a natural sequence of the thrombotic variety, *i. e.*, the clot is absorbed or organized so that its original site is filled with fibrous tissue. In this type there are, as a rule, no further subjective symptoms than an incessant pruritus, well-marked at night and after physical exercise. The third variety of the external, *i. e.*, the venous, borders very closely in its anatomic appearances upon the type of internal hemorrhoids known as the columnar, pedunculated or venous. In this variety of external piles there is an involvement of the mucous membrane and skin of the anus; the veins are dilated, and the mass may consist of but a single set of vessels or be of such dimensions as to almost completely surround the anus. The symptoms of this variety, barring inflammation and ulceration, are those of a protrusion non- or partially reducible, not painful and not bleeding except when inflamed or ulcerated. The internal class may be divided into two varieties: the capillary, or bleeding, and the columnar, venous, or pedunculated. The capillary pile is never seen externally except in cases of relaxation of the sphincter or of dilatation of this muscle. These piles resemble masses of deeply congested mucous membrane, and bleed upon contact of the finger or fecal mass; in fact, they resemble masses of healthy granulation tissue. They are seen upon the use of the speculum and proctoscope, and ordinarily present no evidences to digital examination; blood is seen after each movement, varying in quantity from a few drops to several drams. In addition to the local evidences, all of the manifestations of anemia are frequently seen, while the patient presents a subjective chain of symptoms which are entirely of anemic origin. This variety will eventually result in the columnar type. The second, or columnar variety, usually known by the names of venous or pedunculated, are made up of a mass of dilated veins and one or more arterial twigs. They protrude upon straining or defecation, and are readily reducible, except in case of neglect, when they are liable to become strangulated, edematous, or undergo ulceration and slough. Should any of these changes occur, it then assumes all the evidences of an inflamed pile. These pedunculated piles can be felt upon digital examination, and seen readily with the use of the speculum or proctoscope.

In examining the patient externally, the Sims position is the best, provided that the buttocks are well separated and the patient strains as though about to have a movement from the bowel; when this is done, almost an inch more of the mucous membrane will be protruded than when in the stooping position. For digital examination, either the lateral or dorsal position of the patient is satisfactory. The finger should be protected with a finger-cot, thoroughly anointed with some bland lubricant. Gentle pressure is then made upon the sphincter until its rigidity is overcome. These finger-cots are so thin that the tactile sensation of the finger is not impaired to any extent, while, in addition, they protect the physician from infection and keep the examining finger clean. For speculum or proctoscopic examination the bowel should be thoroughly clean, and in all sensitive cases anesthesia should be produced. Anesthesia permits of a complete examination being made with a view to locating fistulæ and ulcers, which are frequently present in these cases.

The removal of the cause of hemorrhoids will very often be followed by the disappearance of the pile. This is often seen in cases of cured retrodisplacements, stricture, enlarged prostate, stone in the bladder, etc.

Little can be said in favor of medicinal treatment effecting a cure, but with proper attention to the diet and the regulation of the bowels much can be accomplished in relieving the patient of his misery. The venous variety of the external class is frequently

benefited by applications of cold water once or twice daily, while in the capillary variety a suppository of some strong astringent or an astringent ointment has proved curative in my hands. I am accustomed to use a suppository in these cases composed of the following ingredients:

℞ Ferri subsulph. . . . gr. ¼ to ½
Ext. stramonii . . . gr. ½ to 1
Buty. cocoa . . . q.s.
M. Ft. sup. No. 1. Sig. Use at night.

Morphin may be added in case there is much pain.

In the surgical consideration of hemorrhoids the varieties will be considered in the order in which they were described. The thrombotic type, if left to Nature, disappears almost completely by absorption of the clot, nothing but a skin tab remaining. To relieve the patient of his pain and to allow him to attend to his business without loss of time, it is advisable to open the mass and turn out the clot. This is best accomplished by grasping the pile at its apex with a pair of forceps, and cutting off a piece of the skin or mucous membrane, rather than to incise the tissues, as by the latter means it is often necessary to do a secondary operation, caused by the refilling of the cavity, due to primary union occurring in the incision. I have had the misfortune to be compelled to operate a third time in a case treated by incision. After the clot has been extruded, a gauze dressing is worn for a few days until the resulting ulcer heals. As a rule, this requires about a week or ten days. The skin tab variety is a most potent factor frequently of persistent and unbearable pruritus. To alleviate and cure the patient it is my custom to cut off the skin protrusion and dress the bleeding area with sterile gauze.

The third, or venous variety, of the external class is very frequently cured by the galvanic current in the following manner: A needle is attached to one of the poles and introduced into the mass, while the other pole is placed over the sacral or lumbar region. A current of sufficient strength is then turned on and continued long enough to produce a foam at the point of entry of the needle, or a swelling and blanching of the pile. As a result there is a thrombus formation, occlusion of the vessels, with a final shrinkage, and cure of the mass. Allingham's operation has proved the most satisfactory in my hands in these cases. The time of confinement to the house is from three to ten days. The question of anesthetics is a very simple one. It has been my custom in these three varieties to use nothing but local agents to produce the necessary anesthesia for an absolutely painless operation. During the past three years I have given up the use of cocain entirely, and now use a two-per-cent. solution of eucain hydrochlorate. So far no untoward effects have been observed. The anesthesia is as profound, and is as rapidly induced as by the use of cocain, and is sufficiently lasting to allow of quite a protracted operation.

Hemorrhoids of the capillary variety are treated with fuming nitric acid, applied by means of a glass rod, and then followed by washing the pile with water, or they can be cured by touching their entire surface with the actual cautery. The pedunculated variety is subjected to one of three operations, with preference by the author in the following order: Allingham's, or the ligature; clamp and cautery, and Whitehead's, the latter being resorted to only when the crop of hemorrhoids involves the entire pile-bearing area. Following is the technic of operation: The patient should be subjected to a light diet for a few days, a cathartic being given the night before and an enema the morning of the operation. After complete anesthesia has been produced, the patient is placed in the lithotomy position and the sphincter dilated slowly by the successive introduction of the index, middle, ring, and little fingers rather than by the method of introducing the thumbs and using the tuber ischii as means of purchase for making traction. The former method is not followed by the lacerations so frequently seen when the latter method is used, nor is there such a profound degree of after paralysis of the sphincter. The pile is then grasped in a pair of small volsellum forceps, the mucous membrane is incised about the base of the pile, and the submucous tissues dissected up to the pedicle, which contains the vascular supply. Should the pedicle be a large one, then a transfixion ligature is used, and the two portions tied and cut off; in case the pedicle is small, a single ligature is applied and the pile cut off close to the ligature. Recently it has been advocated that the stump be depressed and the mucous membrane be sewed over the stump, the originator claiming that the process of repair is hurried, and that no ulcer forms at the site of removal, provided the mucous membrane unites *per primum*. He also claimed, and very justly, that the danger of fistulæ is reduced to a minimum. This operation can be performed in a few minutes, and has always proved satisfactory in my hands.

The clamp and cautery method has been advocated by its adherents on account of its simplicity, and also because no ligature is used to enclose in the stump the end nerve-filaments, thereby producing an extra amount of pain during convalescence. In this method the pile is seized with a pair of forceps, as in the preceding operation, and pulled well out-

side the sphincter. It is then grasped in the long axis of the bowel by a Smith or Kelsey clamp, applied close to the base of the pile. The portion to be removed is then cut off close to the blades of the clamp, the bleeding edge is seared with the actual cautery, and the clamp is then eased up gradually to see that no bleeding-points are present. If there are none, the clamp is removed. In case there is bleeding the cautery is again applied before the clamp is finally removed. I have had quite an entensive experience with both of these methods, and cannot see any advantage of the latter over the former, but must say that in the latter hemorrhage is more liable to occur in the hands of the inexperienced than in the former, and that when bleeding does occur it is extremely difficult to grasp the bleeding-point on account of the retraction that takes place. In one case in particular in which this occurred I was called in by a fellow practitioner to check a very free hemorrhage in a patient upon whom he had operated the evening before. It is not advisable, owing to the tendency to stricture formation, to remove the entire mucous membrane by this method, but to leave narrow bands of the mucous membrane between each point of operation.

The Whitehead operation is indicated in cases where the entire pile-bearing area is involved, and in which either of the other operations would require the complete removal of the mucous membrane. In this operation the mucous membrane is incised around the entire anal margin, care being taken not to involve the skin; then a dissection is made extending up the bowel under the mucous membrane to a point just beyond the upper margin of the piles. This dissected portion is then excised and the edge of the intact mucous membrane is sutured to the skin margin of the anus. Owing to the extent of this dissection, the hemorrhage is often quite profuse, but is not difficult to control. Objectional features offered in this operation are the great area exposed to sepsis and possibilities of non-union of the tissues, and as a result stricture formation. My individual experience has been limited to few of these operations, but my observations upon numbers of these cases operated upon by others have more than convinced me of the tendency and danger of stricture formation. The patients so operated upon are usually required to remain in bed from two to three weeks.

The treatment by injections of carbolic acid and oil, or ethereal solutions of iodoform, have never appealed to me in any sense but that of torture, as the pain induced by injections is frequently more lasting than that following any of the operations mentioned. The danger of abscess, ulcer, and fistula is too great, while the permanancy of cure has not been sufficiently established to warrant recommending this method.

Attention should be directed in all post-operative cases to the proper regulation of the bowels, restriction of the diet both as to quantity and quality, exercise in moderation, and the change from a sedentary to a more active habit; otherwise, numbers of these patients who have been operated upon will return with a new protrusion which they consider a result of an incomplete or rather an imperfect operation.

SHOULD NON-ABSORBABLE LIGATURES BE DISCARDED IN GYNECOLOGICAL SURGERY?[1]

By R. STANSBURY SUTTON, M.D.,
OF PITTSBURG, PA.

Surgeons, antedating 1845, with the single exception of Nathan Smith, had used only silk or linen thread for sutures or ligatures. These materials were not subjected to any process of preparation beyond the application of a coating of septic wax; the suture material, silk or linen, and the wax were all septic. As a sequel suppuration resulted continually. The wax melted away, the suture material absorbed the serum responding to local irritation, and, preserved at the temperature of the living tissues, the suture material, loaded with bacteria, became a natural incubator for bacteria, a focus, or foci, for distribution to surrounding tissues. The ignorance of the older surgeons as to the value of sterile ligature and suture material, and the absence of a knowledge of germicidal chemicals and heat on such material, coupled with the lack of knowledge of antiseptic superdressing and douches is forever commemorated in their writings, by the oft-repeated expression "laudable pus," in connection with the healing of wounds. If this statement is challenged I ask that the statistics of the older surgeons be compared with those of the present generation, not alone as to mortality but as to the progress and process of wound repair.

In these facts are found an explanation of the failure of our illustrious Fellow, Marion Sims, to perfect the operation for vesicovaginal fistula prior to 1845. In the summer of that year, Metanour of Virginia introduced lead wire as a suture material. Sims, well-nigh heart-broken over his failure to establish the vesicovaginal fistula operation, observed a bit of fine brass wire lying in the path between his office and his home. He picked it up and while toying with it received the suggestion of silver wire as a su-

[1] Read in the discussion upon this subject at the Twenty-third Annual Meeting of the American Gynecological Society, held at Boston, May 24, 25 and 26, 1898.

ture material. A local silversmith produced for him a supply of siver wire. With this new suture material Sims succeeded and gave us, perfected, his vesicovaginal fistula operation.

It was a non-absorbable suture, not an incubator, not a great irritator of the tissues, and without the addition of modern antiseptic douche or prior sterilization. It proved to be the lost link in the technic leading to success. To Sims I accord the introduction to modern surgery of silver wire, the first acceptable non-absorbent metallic suture. From 1845 silver wire advanced in favor. By 1863 Sims and Thomas Addis Emmet had adopted it in all operations within the vagina from trachelorrhaphy to perineorrhaphy. At the Woman's Hospital in New York it was the approved suture material. Emmet extended it use, and with it secured the pedicle in twenty-one ovariotomies. It was used in suture of the uterus after Cæsarean section, and finally it came into general use in general surgery.

The popularity of silver wire must after a half century be subjected to a new test in comparison with a new metallic suture made from aluminum bronze. This substance possesses the advantage of greater pliability, can be tied in knots as readily as silk, and is easier of extraction. Iron, steel, and lead wire, may be relegated to another use, namely, to build a fence around the grave of "Laudable Pus."

During the last fifteen years, under the banner of antisepsis, absorbable sutures and ligature material have almost driven metallic suture material from the field of surgery. What are the materials, and wherein lie their claims to adoption or substitution? The difficulty attending the introduction and removal of silver wire, especially its removal under all circumstances, is an objectionable feature. In this lies the great argument against its use, and the great argument in favor of a more pliable, and, if possible, perishable and absorbable material. Standing midway between metallic suture and silk, catgut, and kangaroo tendon is a substance to be considered. This substance known as "*fil de Florence*," or silkworm gut, was introduced about twenty years ago. At first it was used unsterilized. It is but slightly absorbent and practically non-absorbable. I have removed it from the tissues after two years, and found it unchanged. When successfully sterilized it becomes encysted and harmless in the tissues; when buried completely the loop is kept pliable by absorption of serum; the exposed ends of the suture become hard, and cannot be bent over or twisted, as can the ends of silver wire. In the vagina or rectum they irritate or annoy. Excepting in superficial wounds I have discarded it. It still holds a place in Tait's perineal operation, when the ends are outside of the vagina and should be left long. For the drainage of wounds it is a most admirable material. Silk, catgut, and kangaroo tendon remain to be considered. Silk is the simplest and most perfect of all textile fibers. It is the natural product of the silkworm. Its luster, strength, and pliability commend it above all other material for the ligation of arteries or veins; it is after proper preparation superior to catgut within the abdominal cavity. It is slow and uncertain in its non-irritating disintegration in tissues beyond those mentioned. In vaginal surgery properly prepared silk is very satisfactory. In the cervix it may be left without detriment for months. In all the perineal operations, excepting Tait's, it gives excellent results and is easily removed. In vesicofistula operations I adhere to the use of silver wire.

Since 1866, under the influence of Lord Lister, catgut has come into favor. It claim for superiority is that after its introduction into the tissues it gradually melts away and is absorbed. Raw catgut is always septic. All surgeons have not mastered its management, but when it is well prepared, properly sterilized and chromicized, it forms a suture material of great practical utility. It may be left in the wounds, saving time as well as annoyance to the patient. It lessens the surgeon's labors also. It may be the substitute for silk in all vaginal operations. Kangaroo tendon, also an animal suture material, has been much lauded by Dr. Marcy of Boston. So far as I have used it, it has given satisfaction. But I doubt its superiority over catgut.

In 1845 when Sims succeeded with silver wire and noted the absence of inflammation in the edges of the vesicovaginal fistula, and of cystitis, as characterized by a flow of urine "as clear as spring water," he knew nothing of germs and, therefore, did not know the real cause of his success, nor did he know that science would yet make silk do what it had refused to do for him, nor that silkworm gut or catgut would become acceptable suture materials in vesicovaginal fistula operations.

I will not tire you by bringing up the immortal labors of Schwan, Wolf, and others in biology, or Pasteur and Lister along the development and application of these labors to surgery and the antiseptic principle of antisepsis, but will now turn to the practical application of absorbable or non-absorbable ligatures or sutures to the plastic surgery of the vagina as practised in my private hospital. The preparation of the surface upon which an operation is to be performed stands first in importance. If this surface is not properly prepared and made sterile, any operation is handicapped; therefore, after the patient is anesthetized, the vagina is scrubbed out with a ten-

per-cent. solution of creolin in alcohol, with the addition of green soap, then is rinsed out with ninety-five-per-cent. alcohol, then with 1–4000 bichlorid solution, and finally with sterilized water. The vulva and surrounding surfaces are included in the scrubbing process. If a trachelorrhaphy only is to be done, I have no choice in the suture; it may be silver wire, silkworm gut, catgut, or silk; if posterior or anterior colporrhaphy and perineorrhaphy is to be added to the trachelorrhaphy I use catgut for all. If the perineal operation is to be that recommended by Mr. Lawson Tait, I use silkworm gut. In other forms of perineal operations I employ silk or catgut. In vesicovaginal fistula operations I adhere to silver wire. In all operations on the rectum in which suture material is resorted to, silk and catgut will be found to be the best. To revert to the question under discussion, and its answer, it is my opinion that for buried sutures properly prepared catgut is all sufficient. Excepting in the peritoneal cavity it is always superior to silk. Non-absorbable suture—silver wire and silkworm gut—have but a limited range of preference in surgical operations.

SYPHILIS OF THE NERVOUS SYSTEM.[1]

By CHARLES W. HITCHCOCK, M.D.,
of Detroit, Mich.

It is, of course, not the hope of the writer to adequately review so extensive a subject as that embraced in the title of this paper, nor yet is it his expectation to increase the aggregate knowledge of it, but it may not be devoid of profit to call attention to some points which especially tend to make the disease oftentimes obscure and difficult of diagnosis. That the general practitioner very frequently does fail to diagnose, and so to properly treat, cerebral syphilis there will probably be few or none to deny.

In the first place, it is well to recall that syphilis figures very largely, more largely I think than is commonly thought, in the etiology of diseases of the nervous system generally. There are comparatively few forms of insanity in which it does not stand in a causal relation and one writer has gone so far as to claim that tabes is essentially a syphilitic disease, alleging that fully ninety per cent. of cases of this disease date back to a specific origin. Where syphilis is the prime etiologic factor in nervous affections, its effect almost uniformly is to produce an atypical form of disease. It is, therefore, masked under protean forms and it is seldom that two cases follow precisely the same track. The very long immunity, not only from any nervous manifestations, but also from any secondary or tertiary specific troubles, which may follow the initial lesion, not infrequently renders it difficult for the patient to recall the occurrence of luetic trouble, and, therefore, it is likely to be a common source of confusion and difficulty to the careful physician. The wilful, expert, and persistent mendacity so common to the syphilitic patient is also a factor to be dealt with.

Sunstroke, injury, and other inventions of a mind fertile in evasions are not infrequently obtruded by the patient and his friends as the cause of all the trouble. In spite of evasions, denials, and even a most exemplary life for years, it must always be remembered that syphilis of the nervous system may develop at any time, from a few months to thirty years after the primary infection. Cases are on record in which the nervous manifestations have occurred as early as one month after infection, and Fournier has reported a case occurring twenty-five years after.

Gowers says: "Syphilitic disease is a common cause of softening; it is chiefly a consequence of acquired syphilis." As to age, he says: "Half the cases occur between 30 and 40, one-third between 20 and 30, and most of the remainder between 40 and 50. Cases under 20 or over 50 are rare." He further says: "I have met with it as early as six months and as late as nineteen years after the primary sore." Of fifty cases observed by this author, nine occurred between 2 and 3 years after, seven from 3 to 5, nine from 6 to 10, eleven from 11 to 15, and four cases from 16 to 20 years after the initial lesion. The long interval which may thus intervene between the primary lesion and the first symptoms of disease of the nervous system is of great importance and when the period has been long and the secondaries but slight, possibly the initial lesion having been accompanied by but little pain or annoyance, the persistent denial of specific possibilities may possibly be honest on the part of the patient and not seldom throw the diagnostician entirely off the track. Neither should it be forgotten that inherited syphilis may attack the nervous system. Such cases may be seen in infancy or much later in life, cases having been reported at the ages of 8, 10, 14, 18, 22, and 23. H. C. Wood quotes a case as occurring in his practice at 21. Pathology, diagnosis, and treatment are closely connected, for upon the existent pathologic state will depend the symptomatic manifestations and upon the advance which the pathologic lesion has already made will depend possibilities as to results of treatment.

Gumma and arterial disease are perhaps the more common forms of the syphilitic lesion, yet these are not distinctly separable, for it is probably compara-

[1] Read before the Section on Medicine of the Michigan State Medical Society, May 6, 1898.

tively seldom that gumma exists as a separate entity without involving other tissues, aside from pressure and like irritation, and frequently, if not always (one writer says always), the gummatous process begins in the sheath of the arteriole by proliferation of the nuclei which immediately underly the vascular endothelium.

The site of the gummatous process, too, is all-important and may have much to do with the character of the symptoms developed, whether occlusive, merely mental, or paralytic in character, though, of course, the latter point is also quite as largely determined by the stage reached in the specific process. If this has proceeded far enough to cause occlusion of the artery, acute softening may result. "As an isolated change, it is almost confined to the largest arteries . . . and is most common in the internal carotid, middle cerebral, vertebral, basilar, and posterior cerebral." (Gowers.) While the change itself may proceed to the obliteration of a vessel, Gowers tells us that it is much more frequently the case that "when the lumen is considerably narrowed, a clot forms within it and suddenly arrests the circulation, or forms in branches arising from the affected part. The disease consists in a fibronuclear growth in the wall, which causes a nodular projection on the exterior and diminishes also the caliber of the vessel." There may be, then, a simple gummatous deposit, an extensive gummatous involvement of one or several vessels, possibly occlusion and consequent softening, a gummatous meningitis, or a specific meningo-encephalitis. In many cases two or more of these conditions may be present. So much for the more common pathologic conditions.

The symptoms naturally depend upon the pathologic phase present in any given case. While a chronic process may have long preceded the onset of serious symptoms, these may seem to come from a clear sky, *e. g.*, an apparently acute meningitis may rapidly develop, with violent convulsions, and possibly hemiplegia more or less complete follow. It is very frequent that prodromal symptoms, which have great value in diagnosis, have been passed over as insignificant and trivial by the patient and his friends, and the history of their occurrence is accordingly elicited with difficulty. Histories of attacks of irritability, drowsiness, stupor, mental confusion, temporary amnesia, so-called "fainting-fits," apparently causeless headaches, especially with nocturnal exacerbations, any or all, are straws which help the careful diagnostician to determine the direction of the wind. Epilepsy and apoplexy are diagnoses often jumped at and seemingly warranted in these cases, and yet they fall far short of the mark and may leave unaccomplished what might have been done for the patient by an early diagnosis of specific disease.

The prognosis as to what may be accomplished by treatment must, of course, be guarded, for obviously the possibilities will depend upon the length and extent of the gummatous process. The indications are clear to apply antispecific treatment in a vigorous and positive way. If the result of the therapeutic test be attended by an early clearing up of symptoms, it is of course gratifying and may be accepted as a confirmation of the diagnosis. It must be said on the other hand, however, that a failure of the symptoms to ameliorate under treatment by no means affects the validity of the diagnosis, and this is true for reasons already alluded to. In this connection it is interesting to note that Wood regards it as corroborative of the diagnosis that the patient bears well large doses of the iodids, believing that non-syphilitic patients will not bear this treatment without showing a good deal of irritation therefrom. I mention this point for what it may be worth.

Treatment may fail to show the results desired, especially in advanced cases. If a hemiplegia be due to structural changes which have gone so far as to be permanent, entire relief cannot at so late a date be reasonably hoped for. Well-marked paralyses, however, and somnolence and stupor, which have lasted weeks and even months, have repeatedly cleared up under vigorous treatment. While it is characteristic of a hemiplegia due to specific causes that it is seldom complete, this cannot be accepted as an invariable rule for such hemiplegias are at times entirely complete.

I desire to report the following case as confirmatory of some of the points already alluded to in this paper:

Soon after eight o'clock one morning last fall, I was called to see Mr. P., who, I was informed, had just been paralyzed. He is forty-three years of age, a business man, and has every outward appearance to the casual observer of a man in vigorous health. I knew of his having sustained an injury about eight months previous, and while he had recovered from its immediate effects, there having been a fall and contusion about the left hip, he did not regain vigorous health after it and perhaps naturally attributed many of his symptoms to this accident.

When I first saw him it was about an hour after his first attack. He looked a little flushed, was lying on a lounge on his left side, and greeted me almost hilariously, saying, "I'm all right," and gripping my hand vigorously with his right hand. I inquired as to his right leg and he lifted it vigorously and quickly, showing excellent motor control of it. He said that about an hour before, while attending to a matter of business, his pencil suddenly fell from his right hand. He picked it up, but dropped it

again and repeatedly, and in a few minutes found that he had no use of the right side. He was helped into the open air and soon after into a carriage and was driven home. As I have already said, an hour later when I first saw him control of the right side was good. The paralytic symptoms later increased and at 6 P. M. the same day he had but little, though some, use of the right side. Clonic convulsive movements of that side had continued at intervals throughout the day. The next day paralysis of the right side was practically complete. Here clearly was a condition not due to a sudden apoplexy. He was inclined to attribute all of his troubles to the accident which had occurred eight months before, a view with which I was unable to agree.

I find that he has been married twenty years, and that he has two children aged twelve and fourteen, who are apparently perfectly healthy. The family history is negative. He at first vigorously denied the possibility of syphilis, but finally admitted having contracted a suspicious venereal lesion at about his twentieth year, which he says the doctor told him was not syphilitic. Careful questioning, however, threw serious doubts upon this diagnosis and brought out the fact that some years later he was obliged to consult a physician for what was called and treated as "catarrh." At this time there was a noticeable falling in of the bridge of the nose, undoubtedly due to syphilitic disease of the nasal bones. He claims to have been well with this exception throughout his married life and to have been perfectly correct in his habits during this time. Persistent and further questioning as to the symptoms since his accident and the query as to whether he had ever known such symptoms before the injury seem to inspire his memory and he admits that he has had occasional attacks of mental confusion for a year, perhaps, and I learned that his wife has noticed these attacks for a much longer time, two or three years, in fact. At these times he would repeat the same thing two or three times, was very irritable, and was disposed to be very profane, something quite foreign to his usual habits.

I find that one alleged specialist in diseases of the nervous system treated him for two years or longer for "nervous trouble" without ever suspecting the presence of specific disease, and last summer he fell into the hands of a homeopathic practitioner who told him that the case was too complex for him to undertake single-handed and so summoned to his aid a homeopathic neurologist, but no diagnosis of specific disease was apparently made out.

On further inquiry I find that some four years ago in his business office he showed attacks of marked aberration of memory, when he could not recall events of the day before nor letters written that same day. I am unable to learn of marked convulsive attacks. He has never fallen at home, but in his office has nearly fallen two or three times, only the timely assistance of others saving him from a fall. At home, it has been noticed two or three times during the last year that his speech seemed unusually thick. These attacks would pass off in from one-half to three-quarters of an hour, and there was no loss of motor control attending them. Throughout the summer of 1897, however, he at times had had difficulty with the right side while walking, had less control of that side, and the right foot was clumsy.

Aphasia was only partial when motor hemiplegia was complete, or nearly so, and the speech soon improved. At 6 P.M. on the day I first saw him his pulse was 80, soft and regular, and temperature 99.4° F. At 11.30 A.M. next day, pulse 67, of like character, and temperature 98.2° F. For the next ten days the temperature, at times normal, was more frequently 99.2° to 99.4° F.

My diagnosis of hemiplegia due to specific disease was based primarily upon the history of suspicious infection, which was confirmed by his later alleged "catarrh," upon his history of prodromal attacks of mental confusion, irritability, temporary amnesia, and tendency to convulsive attacks and his age. My prognosis, owing to the long period covered by these prodromal symptoms, was necessarily guarded. I expressed my belief in his ultimate improvement, though to what extent the paralysis would disappear, no one could say.

He began at once to take sodium iodid, 20 grains, three times daily, and this was soon increased to double the amount. He also during two months received a daily inunction of 30 grains of mercurial ointment. After a week he began to move the right hand and there has been gradual improvement in motor control since that time.

His mental phases have been more difficult of management, and these cases, in this respect especially, often tax the resources of the most fertile therapeutist. After a steady and vigorous pushing of the antispecific treatment for two or three months it was gradually diminished as I feared the iodids had to do with the increasing intense nervousness and irritability which annoyed him exceedingly. At these times inhibition was practically *nil*.

Attempting to control this state by 5-grain doses of trional at intervals of four hours through the day, I had a most unusual experience. On calling to see my patient on the day following the giving of this prescription I was greeted most hilariously; he told me he was "fuller'n a tick" and his actions confirmed his statement, for they were characteristic of a man moderately drunk. He confided to me that it was "the cheapest drunk he had ever had," and that he "felt bully." I mention it because it seems to me a very unusual effect of the drug, especially of so small a dose as 5 grains.

Faradism was most acceptable to the paralyzed side and it has never failed to exercise a most pleasing sedative effect upon the patient, who has improved rapidly of late and now rides and walks out daily though he will always bear marked evidence of the hemiplegia.

I do not feel any the less sure of my diagnosis because a vigorous antispecific treatment failed to entirely clear up the paralysis present. I attribute this failure to the permanent structural changes which had

taken place before I first saw him. I believe that an earlier recognition of the real cause might have saved him from the hemiplegia.

Another case in point, and one which well illustrates the efficiency of antispecific treatment when vigorously pushed, is that of Mr. W., whom I saw only recently in consultation. The patient was not in a condition to give any family or personal history himself and his relatives could add but little information except to confirm a rumor that in early life he had been at one time "pretty lively," and that during the previous six months he had been drinking heavily but had abruptly given up his alcoholic indulgence about three weeks before I saw him. He had had no distinctly alcoholic symptoms.

The patient is fifty-two years of age, a widower, had been married about thirty years; no children; wife had miscarried. He is a business man, having charge of the bookkeeping and the financial end of his business. From those associated with him I learned that for several months he had complained of severe headaches, and that there have been periods of mental confusion and great irritability. He would come home at night and attempt to read the evening paper, but would have to lay it aside, saying that it confused him and that "everything seemed to run together." His headaches were so violent that he repeatedly had to leave his work. I also had other reasons for suspecting that this man had had syphilis years before.

The patient was in a deeply somnolent state, did not recognize me, and responded to questions only by monosyllables, after much rousing, and then only in a half-intelligent manner. He could not complete a sentence nor carry an idea long enough to express it. He evacuated both bladder and bowels in bed without warning. There were no localizing or paralytic symptoms. I diagnosed the condition as cerebral syphilis and advised his physician that he be given potassium iodid, 40 grains, three times a day, and a daily inunction of 30 grains of mercurial ointment, the site of inunction to be changed each day. This advice was followed, with the happiest results. Improvement, at first slow, was steady, and after the first week was marked and rapid. His attending physician reports to me that he is now apparently as well as ever and that he has since married.

The results of prompt and energetic antispecific measures in these somnolent or stuporous cases are often most marked and are as gratifying to the patient and friends as they are to the physician. It is particularly important that a correct diagnosis be made early, that is, before permanent changes have taken place, as in that case only can one hope to obtain satisfactory results from treatment.

A Present to the "Relief."—Dr. William M. Polk of New York has presented to the hospital ship "Relief" for the use of the surgical staff a complete set of surgical instruments valued at $500.

WAR ARTICLES.

THE MORBIDITY OF THE VOLUNTEER FORCES AT CHICKAMAUGA PARK, GA.

By HENRY I. RAYMOND, M.D.,
MAJOR AND SURGEON, UNITED STATES VOLUNTEERS.

In writing you from Tampa, Florida, a few weeks since upon the morbidity of 10,000 regulars of the United States forces during their first calendar month in the field I expressed the hope that at some day in the near future I might make use of that statistical review as a basis of comparison for the morbidity that would be revealed during their first month of foreign invasion, or occupation, of Cuba. The troops being about to sail from Tampa, I was unexpectedly detached for duty with the Volunteer forces at Chickamauga Park, Georgia, and thus my former plan miscarried.

Through the courtesy of the Chief Surgeon of the Third Army Corps, and that of the commanding officer of one of the division hospitals, I am enabled to give your readers a statement and numerical summary of the principal diseases that have affected the troops of the division (say 10,000 strong) during their first month in the field here, and likewise during the first month of existence of this division hospital. It is chiefly, however, upon the so-called preventable diseases that I shall touch, inasmuch as means have been taken to prevent the further occurrence of these diseases among the troops located here by very particular attention to the purification of the water-supply for potable purposes, to a deterioration of which may justly be attributed the enormous amount of sickness in several of the regiments. It is believed that the sick-rate will be greatly reduced for the coming month coincidently with the introduction and use of the Maignon and Berkefeld water-filters. These have been distributed as follows: For each division hospital one of each make; for each ambulance company one of each make; for each division headquarters one of each make; for each regiment ten of each make. The date of distribution of these filters is nearly coincident with the termination of the period of thirty days covered by this report on the morbidity of the troops. Consequently it will be of exceedingly great interest to compare this month's sick report with that of the ensuing month. All the waters of this park have been condemned. They are unfit for use for drinking purposes in their natural condition. Before filters were received boiling of the drinking-water was of course resorted to, but failed to accomplish the desired end. Not but that the boiling destroyed all disease germs but the practice fell somewhat into disuse, because soldiers were averse to the drinking of unpalatable, luke-

warm or unsightly water, and were not thoroughly convinced of the unhealthfulness and suspicious character of the streams in this vicinity and consequently the requirements enjoined were not lived up to nor could they well be rigidly enforced. Now, however, we have had our object lesson and the enormous sick report has awakened a personal sense of the danger that lies in a disregard of sanitary precautions on this score. Since the Maignon and Berkefeld filters have been put into operation in our own camp the men eagerly fill their canteens from the purified water-supply and feel a large sense of security from attacks of typhoid fever, diarrheas, and dysenteries which have afflicted their comrades or themselves during their encampment here. We confidently look for a higher morale and a fuller sense of well being to prevail from this time on.

The report below covers the period from June 10th to July 10th and accounts only for the cases of sickness of such severity as to require hospital treatment. The figures are only approximate but substantially correct. The mean strength of the command for thirty days was: officers, 406; enlisted men, 9477; total, 9883. The number of admissions to the hospital (none being sent there who could possibly be treated at the regimental dispensaries, or as officially designated, "in quarters") was 735. The number admitted to sick report, of course, greatly exceeds the number sent to division hospitals, and in one or two regiments the admissions to sick report for the month equaled or perhaps exceeded 100 per cent. of the regimental mean strength for the month. The result was that something had to be done to greatly diminish this sick-rate or the regiment or brigade would soon be so reduced by non-effectives that preparations for an active campaign would have to be temporarily suspended. The remedy has been prescribed—means for purification of the drinking-water—and it remains to be seen how effectively it can be applied.

Of the 735 men admitted to the hospital about 450 have been returned to duty, about 25 have been sent to Leiter hospital, and 4 have died (1 of typhoid fever, 2 of cerebrospinal meningitis, and 1 of acute enteritis). About 2700 days have been lost to the government on account of sickness in hospital. Among the more serious cases, including the infectious diseases, affecting those admitted to the hospital are the following:

Pneumonia, 14 cases or .14 per cent. of the mean strength.
Typhoid fever, 88 cases or .89 per cent. of the mean strength.....
Acute diarrhea, 84 cases or .84 per cent. of the mean strength.
Malarial fever (intermittent and remittent), 194 cases or 1.9 per cent. of the mean strength.....
Measles, 87 cases or .88 per cent. of the mean strength.
Mumps, 14 cases or .14 per cent. of the mean strength.

I am strongly of the conviction that many of the remittent cases of so-called malarial fever will turn out to be mild cases of typhoid fever, as I can remark from examination of the records that fewer and fewer of the remittent-fever cases are entered on the register as malarial and proportionately more cases of continued fever are classified as enteric fever as the month progresses.

For all these infectious diseases, aggregating 380 cases (excluding 101 cases of measles and mumps), it is not far from the truth to affirm that the drinking-water is responsible. These diseases are preventable, and now that we are bountifully supplied with the means for routing both our invisible foes—the microbes—and those more tangible and macroscopic impurities that irritate the digestive tract, it will be our own fault if we supinely submit to their further inroads. Our warfare, however, must be aggressive, our vigilance unabated. The filters will get out of order; the water details will come in late; muddy water will be hauled because the clear springs are farther distant and the filters will become clogged with the clayey deposit and consigned to desuetude. We must learn the lesson early that it is better to spare two men from our effective strength for keeping the balance of the hundred off sick report than it is to destroy our effectiveness altogether by the neglect of sanitary precautions in the matter of providing an unimpeachable potable water-supply.

A NEWLY DEVISED CAMP SINK, OR LATRINE, FOR THE USE OF PERMANENT OR SEMI-PERMANENT CAMPS.

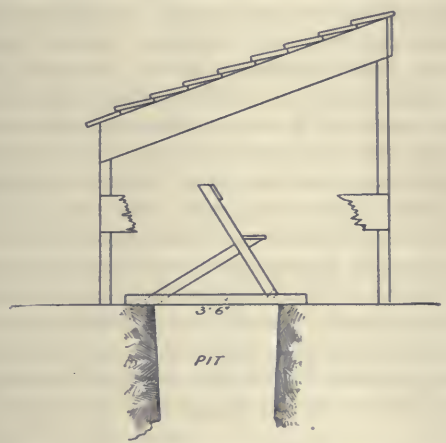
By JOHN McG. WOODBURY, M.D.,
MAJOR AND ACTING CHIEF-SURGEON, FIRST DIVISION, FIRST ARMY CORPS, UNITED STATES VOLUNTEERS.

ALMOST the first thing that arrested my attention on arriving at Camp Thomas, Chickamauga Park, and assuming the duties of acting chief-surgeon of the First Division, First Army Corps, to which I was assigned, was the condition of the sinks and latrines. These, to the number of seventy-three, I regularly inspected every day, and after much hard work got them into something like order and properly policed. Their filthy condition and the carelessness in policing I found mainly to arise from the lack of knowledge of the regimental surgeons as to a proper method of construction, the ignorance of the line officers as to the necessity of absolute cleanliness, and the prevailing carelessness of the men themselves, who, imagining that they would be ordered to the front at once, and ignorant of the fact that they were in a semi-permanent camp, let go every thought for the morrow, and became indescribably filthy in these matters.

After repeated inspections and calling of the attention of the regimental surgeons to this state of affairs, together with a careful pursuit of the line officers made me aware of the fact that in our army, at least, no regular method of construction was followed, and the literature on the subject being very scanty, I set myself to designing a sink for this purpose, which in this country where lumber is cheap, can be built for companies for $3.50, and for battalions for $5 each.

As the new regiments came in they were given a blue print of the design and a typewritten copy of the instructions, while for those on the ground when the old sinks were filled and new ones found necessary, they were built on this plan, save in the case of one of the Pennsylvania regiments, which came into camp splendidly equipped with shelter-tents to cover their sinks, and six-feet-high modesty-pieces hung to the poles. These they had had in use for some years, and so only the pit and seat were necessary for them. This uniformity in construction as well as the simplicity of the method of the same renders inspection easy, and when the absolute necessity of cleanliness had been forced upon the

Fig. 1.

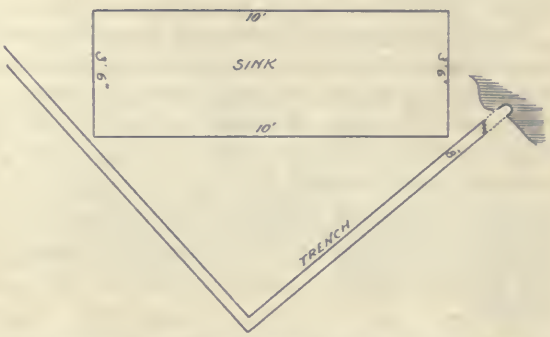


Elevation of shed, seat, and sink of latrine for permanent camps.

minds of officers and men, the latrines were readily kept in order. The policing consists of covering the dejecta of the men to the depth of four inches every six hours with earth, and when it can be obtained, an inch of unslaked building lime. As is well known, the common house-fly lays its eggs and the larvæ are developed in human feces as in the dung of horses, so that the transportation of many micro-organisms, such as those of some of the enteric disturbances, yellow fever, etc., is possible by means of these pests. The addition of the roof to the sink is much to the comfort and health of the men, who in wet weather, especially at night, will seek any shelter for such purposes rather than expose themselves to the elements. In addition to this, they are more certain to keep clean by making use of a well-constructed and comfortable sink than one carelessly or uncomfortably built. The man with typhoid fever who uses a camp sink, and who through careless policing leaves the sink with soiled hands, can transmit through the medium of handling a drinking-cup the germs of his disorder.

The accompanying plans for the construction of sinks are for company and battalion arrangement. The company sink calls for a pit 10 feet long, 10 feet deep, 3 feet 6 inches wide at the surface, and 2 feet 6 inches at the bottom. The battalion sink doubles the length with the same depth and width. These are protected from the flooding of surface water by a chevron-shaped ditch with the apex to the highest ground, and carried well to the rear on the wings. This ditch should be eight inches deep, and

Fig. 2.



Arrangement of drainage-trench for permanent camp latrine.

the excavated earth should be thrown to the inner side and there embanked. Over the top of the sink are placed three transverse pieces of lumber, "bed-pieces," 2 by 4 inches and 6 feet long. Upon each of these is raised an inclined support composed of two pieces of lumber, 2 by 4 inches, the piece at the front having an inclination of 120 degrees. The one at the back meets the one at the front so as to cross it at a distance of eighteen inches from the bed-piece, thus forming the support of the seat. At this point of crossing they are securely fastened together, and the back one cut at a mitre, so as to have the mitred face parallel with the bed-pieces. Upon these mitred faces of the back supports is stretched a strip of board 1 by 6 inches wide, forming the seat. At the top of the front pieces is also stretched a strip 1 by 6 inches, forming the back. This back prevents the possibility of falling into the sink backward from the seat.

This arrangement of bed-pieces, inclined supports, seat, and back being securely fastened together, can be readily removed to a new sink when

the old one may be filled or disused for any reason, as it is light and strong. The broom-scrubbing of the seat with 1 to 1000 bichlorid-of-mercury solution every day will keep the seat free from vermin, filth, etc., as it is easily accessible in every part.

This sink, seat, and excavation is protected from the elements by a shed formed of 2 by 4-inch scantling and boards 5 feet high in the rear and 7 feet high in front, 12 feet long and 8 feet wide, having face-board diagonals as shown in Figure 1; also, a rail 3 feet from the ground on the upper side, formed for the purpose of security of the sink to visitors at night, and also for support of a screen or modesty-piece. The proportions of the shed or cover are sufficient to allow of men passing one another between the seat and front rail, and long enough to allow of standing at urination at the ends. The uprights at the sides of the shed are bedded on two strong pieces, eight feet long, which hold the structure firmly, permitting its bodily removal to another position.

The screen or modesty-piece may be made of canvass or cotton drill tacked to the guard rail and allowed to fall to the ground, forming an efficient protection from view. The cost of lumber is about $4, at a price of $15 per 1000 feet. The low cost, ease of cleansing, ease of transportation, the simplicity, strength, and ease of policing are the features which especially recommend it. The necessity for its adoption in a permanent or semi-permanent camp is obvious.

THE CONDITION OF THE SICK AND WOUNDED IN THE SANTIAGO CAMPAIGN—INEFFICIENCY IN PROVIDING HOSPITAL SUPPLIES.

[Special Correspondence of the MEDICAL NEWS.]

SIBONEY, CUBA, July 8, 1898.

I HAD expected to send you a letter dealing with matters in general aboard the magnificent floating hospital ship "Relief" but a day or two spent on land at this place, and the sights seen here, compel me to leave the pleasanter page of the "purple testament of bleeding war," if there is such a page, and to tell a plain, unvarnished tale of criminal incompetency, of untold, unnecessary suffering, to give a chronicle of treatment of the soldier which would disgrace a Hottentot or a Turk.

I know that this peroration smacks of the sensational, and possibly, may seem hysterical. Well, here are the cold, hard facts, which can be proved and are attested by dozens. To go back a bit: our troops were kept packed like dried mackerel on the transports under a broiling sun in Tampa Bay, from one Tuesday until the next, when they started on their journey to Cuba's southern coast, where they arrived just one week later. Many of the transports were dirty, rotten old boats, and horribly crowded. The "Yucatan," for instance, carried 1500, the allotted capacity being 800 at the outside. This is a fact, as the Rough Riders can attest. The delay at Tampa was attributed by the War Department at Washington to a Spanish fleet. This your readers will remember. The truth is, the water-tanks of many of the ships were foul and even the Department above-mentioned did not dare to send troops to sea without water, though they have no hesitancy in sending them to battle without food, as I shall show. Having, by the help of God and the elements, arrived at Baguiri, they were rushed pell mell to the front with three-days' rations. Other commissary stores were ordered to follow, over roads that were bridle paths and over a country which is a thicket. These poor fellows were hurried to the front, most of them in clothing more suitable for Nova Zembla, and with an outfit sufficient for an Arctic expedition.

The fact that they were thrown into battle without their field-guns does not interest us medically; I merely mention it in passing. After the first three days they had to get along as best they could, sometimes with stores, oftener without. Here is a statement of two of Roosevelt's Rough Riders. I know the men—they are gentlemen, and God knows have proven themselves brave men, "as in suffering all who suffer nothing." They came today into this place to get ammunition for their machine guns from Admiral Sampson. I remarked that they looked a bit thin. They laughed. They had had, I found on questioning them, nothing to stay their stomachs but one cup of coffee that morning and a little wild fruit for two days, but they did not complain. After the terrible fighting on Friday, when they stopped at sundown, these same two men and many of their companions went to sleep after a supper consisting of a cup of hot water, which they had heated in order to get something into their empty stomachs. There was nothing for them to eat. This story applies not only to the Rough Riders but practically to all the troops. They were rushed forward, fighting every step of the way, anyhow, any way, and as Mr. Steppings Wright, the correspondent of the London *Graphic*, said to me, it was a merciful thing they had such an enemy as the Spaniards to fight; not that the latter did not fight and fight hard, but they fought only when they were compelled to do so, only when cornered.

In the three-days' fighting upward of 2000 of our troops were killed and wounded, and this time the unexpected did not happen, the surgeons were swamped—the boasted ambulance corps a thing like the wounded, of shreds and patches. In the first place, in many instances, the field-hospital requisitions had not arrived and the surgeons had nothing but first-aid-to-the-injured bandages, etc. Wounded men were left unattended for hours, while others had to be carried several miles before they reached what by apology was called a field hospital. Stretchers were as scarce as an honest reconcentrado, and mere medicines were conspicuous by their absence. This all sounds pretty bad but the statements are those of soldiers, officers, and correspondents.

I desire just here to state that for this disgraceful condition of things the Medical Department of the Army is

not responsible. Everything that human ingenuity could suggest, and intelligent scientific effort could direct had been done by the Surgeon-General, but the answer for all this bungling is not to be read, as the Germans say, "In the stars," but in the office of the Secretary of War. He who runs may read, and the hundreds of political appointments to staff positions and in the Commissary and Quartermaster Departments quite sufficiently explain the hideous lack of preparation and the absolutely insane manner in which this business here has been risked, and the consequent suffering entailed upon as brave and uncomplaining a lot of men as ever faced a foe. An instance, not medical, but still of interest, as illustrating how things were and are being done: It seems a small thing to the laity in New York to read that the cavalry have been sent to the front without their horses. Your wiseacre says, "They could not have used them anyway," but how about the men who were sent to an almost hand-to-hand fight with short, cavalry rifles, that have no bayonets. But the battle has been fought and a division hospital established at this place, Siboney, eight miles from the front. I was not an eye-witness to what I have above described. I now come to scenes which I have, I regret to say, witnessed. I do not exaggerate, and what I describe can be vouched for by every one who has been so distressfully unfortunate as to have seen them.

There are now about 300 wounded here and they are constantly arriving from the front. And how? Some limping painfully on improvised crutches, and all bedraggled and exhausted. Others, more seriously hurt, on the back of a stronger though, in many instances, sick or wounded companion, others still on horses or mules, sometimes two on one animal, which is lead by another soldier, for the riders have all they can do to hold on. Many are brought in by ambulances, however. Men came in and went out, or rather, were sent on board transports, without shoes, or coat, or blanket. One poor fellow, for instance, who was wounded in one leg, had been sent from the hospital to the landing-stage for shipment on a transport, and who had been for four hours in the broiling sun, had nothing in the world but an old worn, filthy shirt, and a pair of torn trousers. Of shoes, of course, he had none. He told me there was no one to give him anything, even if such necessities were there. There were dozens of such cases.

And the hospitals: As one in authority said, they are heart-breaking, with scores of men with wounds in every stage of neglect. This applies to those who have lately arrived from a long journey from the front (for the surgeons here are working till they drop) lying on cots, with dirty blankets under them, the passage between the wounded being covered with dirty straw. Flies are a perfect torture to the sick and wounded and there is no attempt made to protect them in any way. This condition of things, I state again, is not the fault of the surgical corps. The wounded and sick were poured in upon them before their supplies had arrived or before they had had time to utilize the materials at hand.

This fact will be appreciated when I tell you that the hospital outfit is on the "Relief" which arrived six days after the first big battle. The sight in these apologies for field hospitals is absolutely and entirely sickening and beyond words distressing. A friend told me that one of the chief surgeons, a friend of his, had at one time broken down and cried like a child at the condition of the men and the hospital which he was powerless to mitigate. I am thankful to say that things are rapidly being rectified, now that the "Relief" has arrived. She should have been here two weeks ago, and would have been were it not for the stupidity and contrariness of a War Department official. The commissary for the sick and wounded "would disgrace a camp of South-Sea Islanders," as an officer expressed it. The poor fellows will tell you, if questioned, for they never complain, that they have had nothing they could eat.

Well, so much for the hospitals here; the memory of their wretchedness will never be forgotten.

They have been sending the wounded and sick North on the different transports; a most excellent plan, but here again the absolutely unpreparedness of things has inflicted great and unnecessary suffering on the troops. This harbor is, in fact, no harbor at all. Most of the time there is a high surf running and the transporting of the wounded from the beach to the ships is only accomplished with great delay and much roughness, small boats entirely unfitted for the transportation of the wounded being used. Of steam-lighters, so urgently demanded by General Shafter, there are none; none for this purpose, at least. The men who are supposed to be ready to move or be moved, are sent to the landing-place to wait their turn to be taken to the ships and here they frequently remain hours and hours in the baking sun on the sand. It is indeed a pitiful sight. I saw to-day, any number of men, most of them more or less seriously wounded, and many of them unable to move, who cried like children when I asked if I could not do something for them. The reply most always was: "Get us on board that white ship (alluding to the "Relief"), please do, sir." I am thankful to say that now the "Relief" has gotten to work they are being taken aboard tenderly and properly cared for by the surgeons and nurses. As one poor fellow, who was terribly wounded said, "Oh, doctor, this is heavenly!"

As you know, the "Relief" is commanded by Dr. George H. Torney. He it was who fitted her out, and now directs her, and many a blessing he'll get from the soldiers and officers cared for on this ship. Our only fear is that there will be many more wounded than the "Relief" can hold. The truth is, we should have several of these hospital ships; the Government can well afford it. Whether those in Washington, who, as the Germans say, "run things from behind the green table," will, in their infinite wisdom see fit to provide such a practical blessing, while devoutly to be wished, is scarcely likely of fulfilment.

Officers from the front tell me that the condition of things along the line of battle is too horrible for words. The Spanish left their dead and wounded, many of them on the field, and the stench is something awful. Hundreds of their wounded must have died a lingering death where they fell.

The Spaniards, as you remember, did not mutilate the bodies of the Marines, as at first charged. They have not, however, respected the Red Cross, and have repeatedly fired upon the ambulances, upon wounded men on stretchers who were being carried behind the lines. It seems that sharpshooters, clad in the uniform of our soldiers, which they had stripped from the dead, were hidden in trees and, from that point of vantage, would pick off the wounded, and the hospital stewards and surgeons who were carrying them.

FRANK DONALDSON, M.D.

OUR PHILIPPINE LETTER.

GUNSHOT WOUNDS AS SEEN IN THE PHILIPPINES.

WITH ADMIRAL DEWEY'S SQUADRON, OFF MANILA, PHILIPPINE ISLANDS, June 22, 1898.

THE insurgents' headquarters being at Cavité, Aguinaldo has established a hospital in an old convent in which both his wounded and those of the captured Spaniards are treated. Considering that very great humanity on both sides has hitherto been an unknown quantity, the greatest praise should be given to the natives, not only for their treatment of captured sick and wounded, but also of their prisoners.

Two native doctors comprise the staff of this hospital, and for attendants they have several medical students who had studied in the hospitals at Manila. There are many reasons why wounds treated in this hospital should do badly. The building itself, situated in the center of Cavité and shut in on two sides, is a typical Spanish house as seen in the tropics. Thick walls of stone, with here and there a small window, keep the fierce heat of day from penetrating, but in its place it substitutes a dark, damp coolness with but little ventilation. When the hospital was filled with men who had been in the field for several weeks, having wounds discharging fetid pus, this heavy, foul air must have certainly affected the progress of healing. The depressing influence of heat, of defeat, and more especially the question at first if their lives were to be spared, are important factors in the cases among the Spaniards. It is also necessary to remember that the wet season is now here, and with it the usual fever which has complicated many of the cases. As regards food, medicine, and dressings, everything possible has been done, but all of these essentials have been limited. With so many prisoners to provide for, beside his own men, General Aguinaldo has only been able to furnish a coarse bill, with now and then a little beef and bread. Those of the wounded who had money were able to buy plenty of bananas and mangoes or a cheap wine. Dressings were at first very difficult to obtain, so that infected wounds got a good start.

A lack of surgical instruments among the doctors at the hospital was the opportunity that allowed some of the surgeons from the fleet to treat the more urgent cases, and to get a record of the remainder, consequently patients who were doing well were but superficially examined out of courtesy, and a desire not to interfere with previous treatment. The character of the bullet could only be judged from the wound of entrance, except in cases where extraction proved beyond any doubt, the majority of these being the Mauser, and several of caliber .45, probably the old Graus or Collonbaim.

Most of the men were wounded during the battle around Bakor, where more than 2000 Spaniards were repulsed in their endeavor to relieve some of their comrades besieged in a church near old Cavité. Aguinaldo placed the total number engaged in this battle at about 3500 or 4000, and claimed only 25 killed and 70 wounded, but as exact figures are hard to obtain these must be taken cautiously. The number of Spanish dead is not known, and their wounded seen in this hospital amounted to about 50. Without doubt many wounded escaped; still, making all allowances, the number disabled on both sides, for so many men engaged, was very small.

The amount of destruction that the modern rifle apparently is capable of is theoretically much greater than practical tests go to show. One naturally presumes that the greater range, velocity, and flatter trajectory, not to forget rapidity with which the bullets may be fired from these magazine rifles, would tend to cause many more wounded and killed than was the case with the old single-loader. No doubt that modern field tactics account for part of this discrepancy, and especially is this to be considered in the following cases, for nearly all the fighting between the Spaniards and insurgents, up to the present time has been by an extended skirmish line, in which the rebels, by a series of rushes, would quickly advance, sheltering themselves at every opportunity, until with a last desperate rush the Spanish position would be carried.

The following is a report of the principal cases of injury:

Gunshot Wounds of the Head and Neck.—

1. Of jaw. Bullet (Mauser) entered at inner edge of masseter muscle and lodged just back of parotid gland on the right side of face. Suppurated freely. Bullet removed. Had also a sloughing machete wound of right forearm, which produced a secondary hemorrhage that nearly exsanguinated him. Was treated by doctors in hospital with perchlorid of iron on cotton. Under ether the cotton was removed, wound cleaned of sloughs, and bleeding artery caught by forceps, but it was so much gone that forceps came off. Incision along course of radial proved the bleeding vessel to have been a muscular branch of that artery. Radial ligated above wound, and all bleeding ceased.

2. Of jaw. Native woman, shot by accident. Bullet entered just below lip in median line, producing a compound comminuted fracture of inferior maxilla, and then passed through submaxillary triangle to produce wound of exit at side of neck. A superficial cervical abscess formed with rigidity of the neck, and from the mouth protruded a piece of alveolar process with three teeth adherent, and much foul-smelling pus and saliva. Under ether Dr. Brownell removed all fragments of bone and sloughing tissue, opened the abscess, and passed a fillet of gauze from mouth out of wound in neck. Patient doing well, abscess nearly filled up, bone trying to unite in median line.

3. Of jaw. Compound comminuted fracture of inferior maxilla, splitting bone and lip down to mental process. Sloughs and granulations filling the wound. Under ether the sloughs and granulations and bone were trimmed off, and flaps freed and sutured. Operation by Dr. Broderick. Patient did remarkably well, and in ten days was able to talk a little and take semisolids.

4. Of jaw. Entire front of lower jaw carried away by fragment of shell, leaving a foul-smelling granulating wound filled with bits of bone, teeth and sloughs, extending nearly to hyoid bone. Under ether Dr. Brownell removed all bits of bone and slough, trimmed down flaps, and brought together with silver sutures. A secondary etherization was necessary to put in additional sutures to prevent flaps from tearing apart. At the end of ten days patient was doing well, and there was but little discharge of pus on the daily dressing.

5. Right temple. Attempt at suicide, but pistol was pointed too far forward. Bullet removed just beneath skin on forehead.

6. Parotid region. Mauser bullet entered middle of parotid gland on right side, and going beneath zygomatic arch entered orbit, destroying right eye, and producing a compound comminuted fracture of orbital plate and frontal bone. It passed directly through frontal sinus to exit in middle of forehead. Under ether, the right eye (what was left of it) was removed, wound-track cleansed and irrigated, and from parotid gland to orbit a heavy silk suture was passed for drainage, while a rubber tube was placed through wound of frontal sinus to orbit. Previous to this operation it had been necessary for me to remove the left arm at the middle of the humerus, because of a beginning gangrene from a compound communited fracture of elbow-joint. Amputation stump healed kindly, but the wound of the head suppurated freely, even with constant irrigation and dressing. At time of removal to Manila he was very weak and in a bad condition.

In addition there were five cases of superficial injury.

Gunshot Wounds of Chest.—

1. Left chest. Ball (Mauser) remains. Entered just above the heart, and a forming abscess over left scapula probably denotes its location at present.

2. Right chest. Hemoptysis and death.

3. Right chest. Ball remains (Mauser). Also muscle wound of left arm. No fracture.

4. Left chest. Ball remains (Mauser).

Gunshot Wounds of Abdomen.—

1. Through liver. Ball entered at seventh interspace, mammillary line, and came out at the back. Patient up and about June 15th, and both wounds healed.

2. Left gluteal fold, exit two inches on the right of the umbilicus (Mauser).

3. Through abdomen and descending colon (Mauser).

4. Crest of left ilium.

5. Left ilium.

6. Superficial wound of right side from bit of steel jacket of bullet about the size of a finger-nail. Its ragged edges tore a large hole in skin, just beneath the liver, and then it buried itself in muscle from which it was easily removed.

Gunshot Wounds of Upper Extremities.—

1. Right forearm, with compound fracture of ulna (Mauser). Did very well after it was put up in anterior and posterior splints with "window" for wound to be dressed.

2. Left arm. Bullet brushed across left breast producing a superficial wound. It then entered inner side of left arm, fracturing the humerus, and coming out at front of the arm. When first seen the wound was full of pus, but simple irrigation and putting up in splints, with daily packing of iodoform gauze, was able to save the arm. Patient doing well at time of transfer.

3. Right hand; superficial wound at dorsum, cutting the extensor tendons, and producing wrist-drop. Wound dressed, and hand placed on a straight palmar splint.

4. Right elbow, ball (Mauser) entering on outer side of arm above elbow, and after shattering joint, produced a large, sloughing wound of forearm, with great swelling and infiltration. Under ether the arm was amputated by Dr. Brownell at junction of lower and middle thirds. Amputation wound suppurated and partially sloughed, but at time of transfer he was doing well, with wound nearly closed.

5. Right elbow; ball tore across tip of olecranon process, shattering the bone, and producing a large, sloughing wound, but not opening the joint. Wound dressed and put up with internal angular splint.

6. Left arm; compound comminuted fracture of upper third of humerus, with free suppuration, and the arm badly swollen. Under ether Dr. Brownell amputated at shoulder-joint. Patient had severe shock after the operation, but soon rallied, and at time of transfer the wound was nearly healed.

Ten other wounds of the upper extremity, received for the greater part from Mauser bullets, were superficial in character, and the patients have made rapid recoveries.

Gunshot Wound of Lower Extremities.—

1. Compound comminuted fracture of femur (left) at trochanters. Attempt made to save leg, but having been badly put up, even if it had been a single fracture, it would not have healed. Under ether the thigh was amputated at joint by Dr. Brownell, and patient rallied well from operation. He died the next day (June 11). Examination of bone showed an extensive comminution (Mauser).

2. Right buttock; sinus explored under ether, and the ischium was found to have a cleanly cut perforation. No symptoms of injury to pelvic viscera. At the end of five days an abscess was indicated over buttock that discharged of itself, carrying a Mauser bullet with the pus. He had, also, a superficial wound of entrance and exit on the same leg from another bullet.

3. Head of tibia. Ball entered just above fibula, and crashing through cancellous tissue of head of tibia, split off a spiral fragment on inner side. An osteomyelitis suppurativa resulted, and a purulent synovitis followed, with swelling of leg and bogginess of knee-joint. Under ether the thigh was amputated at junction of middle and

lower third. When the anterior cut through the muscles was made, a pus-pocket was opened in the muscles where the purulent synovitis had extended under quadriceps tendon. This was cut out of flap, and operation finished according to usual methods. Suppuration occurred, but patient was doing well at time of transfer. Operation performed by Dr. Brownell.

4. Left thigh. Compound fracture. Had been placed in faulty position; this was corrected, and extension was applied. Wound (Mauser) leading to bone ran from upper and outer side of thigh to middle and inner side.

Eighteen superficial wounds of the lower extremity were also reported in addition to those above detailed. The patients have made good recoveries.

In the above cases the predominance of wounds of the extremities cannot fail to attract attention. Without doubt many of the killed received injuries to the head, abdomen, or chest. Still, this explanation will not answer for the discrepancy, and it seems rather to be due to the manner of fighting, in which every tree, bush, or rock furnished a means for protection to head and trunk. Arms and legs are more difficult to conceal, and several of the wounded told me that in that way they had been shot. This excess of gunshot wounds of the extremities I found to be true among the wounded Greeks, in the hospitals at Athens, when I visited them last summer just after their war with the Turks. The manner of fighting had been similar to that in the Philippines.

Another curious feature among the above cases is the ease with which a muscle in contraction, or any slight obstruction, will change the course of the new bullet. This was a common fact in regard to the old soft bullet, but experiments on the cadaver with the steel-jacketed bullet seemed to show a clean perforation of all tissues, including bone. This was only found to be true in one case as regards bone, all the others being fractured.

The scarcity of secondary hemorrhage is remarkable considering the number of suppurative wounds.

The amount of shock is not to be accurately estimated, because of the lapse of time before the men reached the hospital. After the operations, in which the patient was generally under an anesthetic an hour, it was a curiosity to us all to see the rapidity with which they would rally, and soon call for the inevitable cigarette. The pulse indicated considerable shock in most severe cases, but several of the men were better afterward than before.

In connection with the gunshot wounds there were several cases of troublesome machete wounds, because of the nasty sloughs that would occur. The machete is a short sword with a heavy back, and enters the tissues more by its weight than keenness, and in so doing bruises the tissues. There were twelve of these wounds altogether, involving, for the most part, the head and upper extremities.

The final results of all the cases here detailed will not be known, as most of the men were transferred to Manila on June 19–20th, under the Red-Cross flag, by the permission of Aguinaldo. The hospital contains at the present time only a few men down with fever and the insurgent wounded. Most all of those wounded in the lesser engagements during the month have been divided between three other hospitals, which the insurgents have in smaller villages.

In conclusion, the possibilities of the campaign of our troops show that even in this hot, moist climate severe suppurating wounds may heal kindly. What such wounds will do if properly handled from the first yet remains to be seen. That so many of the Spaniards had fever points to what we may expect among our soldiers.

DUDLEY N. CARPENTER, M.D.,
Assistant Surgeon, United States Navy, on board U. S. S. "Raleigh."

MEDICAL PROGRESS.

Thrombosis of the Mesenteric Veins.—KOESTER (*Deut. Med. Wochenschr.*, May 26, 1898) puts on record three cases of thrombosis of the mesenteric veins, a rare affection and one about which little has been written. The resulting gangrene in one case affected the large intestine and in the other two a part of the small intestine. The symptoms were similar to those of a case of embolism of the mesenteric artery, also recorded by Koester. All of the patients died. If operation was attempted it was seen to be hopeless as soon as the belly had been opened. By comparing the symptoms in these cases with those of the ten previously recorded by different writers it is possible to draw a fairly clear picture of the disease. The patient may be attacked suddenly in perfect health, or he may be recovering from some severe illness. There is invariably intense abdominal pain with vomiting and often stoppage of the bowels and collapse. The abdomen is extremely tender, and if the patient outlives the shock, tympanites follows. In a few instances there has been a bloody diarrhea. Death is not long delayed. Sometimes it comes in a few hours. In one case it was delayed for three days. At autopsy a bloody fluid will be found in the peritoneal cavity, thrombosis of a part or all of the mesenteric veins, bloody infiltration of the corresponding mesentery and intestine, or a gangrene of the latter, according to the duration of the trouble. In only two cases has the large intestine been the seat of the thrombosis.

One can only guess at the origin of the thrombosis. Sometimes the mucous membrane of the intestine has been found to be ulcerated; sometimes it has been intact. Some writers have said that the thrombosis is caused by a slowing of the portal circulation owing to existing cirrhosis of the liver or cancer of that organ; but if this is an adequate cause it is difficult to explain why it so infrequently occurs, while these hepatic troubles are so common.

The diagnosis is not to be made with absolute certainty during life. The affection can readily be confounded with acute ileus, or a perforative peritonitis, or even with an invagination, if a distinct tumor does not point clearly to the latter trouble. The most characteristic symptom is the accumulation in the peritoneal cavity of a bloody fluid in a short time, the symptoms above described being present, and malignant disease and tuberculosis being excluded.

SATURDAY, AUGUST 6, 1898.

CRIMINAL INCOMPETENCY IN THE ARMY—PROMPT ACTION DEMANDED.

The startlingly brilliant events which have characterized the present war with Spain have provoked the comment that we, as a nation, are making history fast, and we have laid the flattering unction to our souls not only that we are making it fast but that we are writing it in letters which are large. It must not be forgotten, however, that the facts upon which the philosophy of history depend are frequently found in the foot-notes. The foot-notes which will ultimately determine the picture of this war are now rapidly coming in. First, the "Seneca," with its mortifying tale of wretchedness and incompetency; then the "Alamo," with its confirmation of all that the "Seneca" presaged, and finally the "Concho," which bears its testimony of reckless incompetency and seals the judgment of the Nation that the glory of our arms in battle has been sullied by incompetency due to political favoritism at the seat of government.

The sad record of these transports has called attention to the condition at the front, and we find that the story of the neglect of the sick and wounded does not begin with the log of these vessels, but, commencing with the fighting men in the trenches, who were illy supplied with even the plainest army rations, back to the dressing-stations and the field hospitals, all the way down to the permanent hospitals on the coast, we find the dark trail of incompetency, lack of organization, and absence of the commonest precautions against the casualties which attend a military invasion. In reviewing the events of this brief campaign, there appears to be an utter lack of administrative ability, and the conduct of affairs, instead of being characterized by military precision and discipline, shows a degree of disorder and confusion amounting almost to chaos. The responsibility for this seems to lie wholly at the door of him who placed a sick man in command of this campaign, and supported him with quartermasters and commissary officers who were unequal to their duties. Every one, both wounded and sick, as well as observing civilians and commanding officers, testify to the indomitable devotion to duty and capacity for work shown by the army surgeons in their efforts to care for the sick and wounded. In their emergency-chests, which the army surgeons themselves had sufficient foresight to insist should go with them everywhere, stimulants, antiseptics, first-aid dressings, and surgical instruments were at hand to enable them to do their surgical work and meet pressing emergencies. Chief-Surgeon Senn testifies to the fact that he personally operated in all the field hospitals and always found the essential antiseptics and dressing-material required in military practice. "At no time was there lack of stimulants or anesthetics." It was after the surgeons and the dressers had done their work that the shameful neglect began. Tents and blanket supplies were inadequate. It is true that many of the wounded soldiers arrived at the field hospitals stripped of much of their clothing which had not been replaced after passing through the hands of the field surgeons at the bandaging stations just back of the battle line, where the clothing was removed for the purpose of examining or treating wounds. The supply of extra clothing and blankets was quickly exhausted and many of the wounded soldiers were obliged to lie all night on the wet grass and water-soaked ground half-naked as they were.

That the medical arm of the service is not responsible for this condition of affairs is completely estab-

lished by the letter of Surgeon-General Sternberg which we publish in another column.

But such events must not be allowed to continue. The pressing duty of the hour is to determine wherein the responsibility rests and to correct with prompt and impartial hand the errors and mistakes which have made it possible for such things to occur. Crimination and recrimination between the various departments of the army will not suffice. Let it be understood at once by as stringent a mandate as the President can pen (for we must go behind the tin soldiers and ambitious politicians to some power that can be trusted) that what has happened is the last blunder that will be endured. Let the country have the assurance, by the appointment of men of experience to important positions of trust, that competency has taken the place of incompetency and that devotion to duty has supplanted self-interest and political preferment.

The Porto-Rican campaign gives promise of a bloodless and triumphal march to victory, but in spite of this fact and in the face of impending peace, in order to satisfy the clamor of volunteers and their friends for service at the front, General James F. Wade has been ordered to conduct a provisional division of fifteen regiments of infantry to Porto Rico, although there is no ground of military necessity or high political expediency to justify such a move. The only explanation is to be found in the desire of the Secretary of War to give the several States of the Nation representation in the field. If men are so anxious for military experience and transports are available for so large an army, let them be used in assisting our sorely afflicted men at Santiago, and thus permit the latter to be brought home and recuperated. If properly conducted, fresh troops can be landed and placed in garrison with comparatively little danger. The War Department would be fulfilling its mission better if it directed its attention to such details at the front, instead of keeping so watchful an eye on the political situation at the rear.

YELLOW FEVER IN THE ARMY. WHO IS RESPONSIBLE?

UPON the outbreak of hostilities it was distinctly announced by those most competent to judge that the great danger to our troops in Cuba did not reside in the Mauser bullet or the Spanish guns, but in the diseases which were endemic in the island, and especially yellow fever. It was recognized, however, that if the troops could be located upon the hills, with entire absence of communication or intercourse with the inhabitants of the towns, the danger of yellow fever would be reduced to a minimum. For the scene of a campaign which would be immune to yellow fever, the vicinity of Santiago afforded one of the most perfect battle grounds in all the tropics. The essentials of success in this particular are (1) high elevations, and (2) a complete quarantine against the towns. Weeks and months have been spent at the mobilizing camps in instilling the fact that these two principles constitute the A B C of prevention against yellow fever. The first essential was attained by bringing the campaign to a conclusion with the utmost despatch, so that the troops could be withdrawn at as early a period as possible into healthful camps upon the hills. The second principle, however, was violated with a degree of neglect and inattention that was little short of criminal.

Now that attention is withdrawn from the actual fighting and an analysis is being made of the conditions existing during those exciting days in the rear of the firing lines, it is discovered that sympathy for the reconcentrados entirely supplanted consideration for our own troops. Barriers of defense against the infected Cubans were broken down, and the hordes were allowed to spread the germs of disease throughout the entire army. It is asserted as a fact by Mr. H. L. Beach, an Associated Press correspondent, that he saw the army ambulances used to haul the sick and squalid refugees who were tramping through the mud from the front to the rear so that they might get food, these same ambulances also being used indiscriminately for transporting the sick and wounded from the dressing-stations and field hospitals. But worst of all is the fact that the commissary wagons were constantly going from Siboney loaded with supplies and returning loaded with refugees. It is a fact that no yellow fever appeared in the army until the lines were opened to these people from Santiago.

From another source comes the startling assertion that the yellow-fever epidemic in the army is chargeable directly to the Red-Cross officials. Mr. William Gray of Washington, microscopist of the Army

Medical Museum, on duty aboard the hospital-ship "Relief," is reported in the New York *Sun* as asserting that the Red-Cross people instead of confining themselves to distributing food among the Cubans, as they had been instructed, opened army hospitals under the charge of the Red-Cross surgeons in the Cuban houses or huts at Siboney, and it was among the troops exposed in these Red-Cross hospitals that yellow fever made its appearance. The responsibility for this unfortunate condition seems to lie with the commanding officers or their medical advisers. The hordes of refugees should have been regarded as a pestilence, and compelled at the point of the bayonet to keep within quarantine bounds. That the first orders to burn Siboney should have been disregarded, and native houses within its limits taken as hospitals, indicates a lack of discipline for which some one should be held to strict account.

TYPHOID FEVER IN CAMP.

The prevalence of typhoid fever in the various mobilizing camps is a source of great concern. It is likewise a serious reflection upon the sanitary authorities who are responsible for the health of these camps. In the whole list of common diseases there is not one which is so thoroughly understood as typhoid fever. The cause of the disease, the channels of its communication, and the means of prevention are so intimately known that its prevalence among a body of men is at once a proof that some one has blundered. This is not a pleasant reflection when we consider that typhoid fever has found its way into every National camp of instruction, and, what is more, has gone with the troops to Cuba and at the present time is responsible for more deaths among the soldiers in front of Santiago than any other single disease. Only two channels of infection need to be watched, *viz.*, the water-supply and the milk, and more especially the former. At Camp Alger, located near the very seat of our Government at Washington, infection occurred early and its march has been constant and rapid until deaths have been reported very frequently. The camp at Jacksonville is passing through a similar experience, as are those at Tampa and Miami. Camp Thomas, at Chickamauga, a great National Park, affording every facility for a perfect camp, has not escaped the contagion. The action of the Government in abandoning these camps and seeking new ones, even at great expense and trouble, is a credit to its humanity, but its should never have been necessary.

A circular letter and brochure, recently issued by the National Relief Committee, though not intended for that purpose, is a severe arraignment of the sanitary authorities. As it says, it may be clearly held to-day that the sacrifice of men, either at home or abroad through the ravages of water-borne diseases is, as a rule, not only discreditable, but is unnecessary and, therefore, unjustifiable. Not only is this committee insisting that all water used by soldiers should be boiled, but is making it easy to provide the soldier also with water that has been submitted to aeration afterward, thus rendering it safe and potable, as well as grateful to the palate.

ECHOES AND NEWS.

The King of Spain Ill.—Special despatches from Madrid report the little king, Alphonso XIII., ill with a mild attack of measles.

The American Electro-Therapeutic Association. — The Eighth Annual Meeting of this Association will be held September 13, 14, and 15, 1898, at Buffalo, New York. Dr. Charles R. Dickson is president of the association, and Dr. John Gerin of Auburn, New York, secretary.

American Climatological Association.—The fifteenth annual meeting of this association will be held at the Maplewood Hotel, near Bethlehem, N. H., on August 31 and September 1, 1898. President, Dr. E. O. Otis of Boston; Secretary, Dr. Guy Hinsdale, of Philadelphia.

A Second Hospital Ship for the Army.—The steamship "Missouri" has been purchased by the Government, and will be immediately equipped as an army hospital ship as a companion to the "Relief." She will be in charge of Major Wm. H. Arthur, Surgeon United States Volunteers, who has been appointed chief-surgeon.

The Disgrace of the "Seneca" Surpassed.—The account of the cruise of the transport "Concho" from Santiago to New York presents a scene of horror which surpasses the mortifying description of the voyage of the "Seneca" and calls for decisive action. An impartial and searching official investigation should be ordered at once.

New York Summer Corps of Physicians.—The New York City Board of Health has appointed the usual summer corps of thirty-eight physicians. The greater part of these were promoted from the corps of school inspectors, and the balance from the civil eligible list. They will receive a salary of $100 per month, and the term of service will expire on September 10th.

Dr. Skinner Shot.—Dr. Erasmus D. Skinner of North

Hempstead, L. I., was aroused from his bed Wednesday night, July 27th, shortly before midnight, and shot by a stranger who pretended he wanted the doctor to call on a sick woman. It is thought by the physicians in attendance that Dr. Skinner will recover, nothwithstanding the fact that he is 60 years old.

A Soldier Dies of Home Sickness.—In a recent dispatch to the Adjutant-General of the army, Gen. Shafter states that a private in the Second Massachusetts Volunteer Infantry had died of nostalgia, or home-sickness. It is stated that during the recent Civil War there were hundreds of deaths from this cause, but this is the first to be reported during the present campaign.

The Tropical Climate Inimical to the Use of the Fluoroscope.—Major Torney, the surgeon in charge of the hospital ship "Relief," reports that the static X-ray plant, installed by the Government on the ship, could not be used in the tropics owing to the atmospheric conditions. The only X-ray plant that had been of any service was the one presented to the ship by the General Electric Company.

The Mississippi Valley Medical Association.—The twenty-fourth annual meeting of this association will be held at Nashville, Tenn., October 11, 12, 13, and 14, 1898, under the presidency of Dr. John Young Brown of St. Louis. Dr. Henry E. Tuley of Louisville, Ky., is the secretary. The annual address on medicine will be delivered by Dr. James T. Whittaker of Cincinnati, and that on surgery by Dr. George Ben. Johnson of Richmond, Va.

The Sanitation of Porto Rico.—General Wilson has been appointed by General Miles Governor-General of Porto Rico with headquarters at Ponce. His first official act was to organize a sanitary corps, and at the head of this he has placed the surgeon-in-chief of his staff, Dr. John McGaw Woodbury of New York. No better selection could have been made. Major Woodbury's reputation for promptness and thoroughness insures the future excellent sanitation of the island.

Hospital Reports from Santiago. — The latest returns from Santiago announce that there are 4280 sick in the hospitals, about one-fourth of the entire command. Of these more than 3000 are suffering from typhoid, malarial, and yellow fever. The last-mentioned disease is of mild type and most of the victims recover. The greatest mortality occurs among the cases of typhoid and malarial fever. About 500 or 600 new cases occur daily and an equal number of convalescents are being discharged.

Appointments in the Marine Hospital Service.—The Board of Medical Officers of the United States Marine Hospital Service recently convened in Washington for the examination of candidates for appointment as assistant-surgeons in the Marine Hospital Service has submitted its report. Twenty-four physicians appeared for examination, of whom five were successful in attaining the required average, and are eligible for appointment. There are at present two vacancies and the two men receiving the highest average will be recommended to the President for immediate appointment.

All Transports Must Have Army Surgeons.—By order of Surgeon-General Sternberg every army transport ship hereafter will have assigned to it an assistant-surgeon of the army, and must carry hospital stores. It is said that the reports concerning the character of the accommodations and the food furnished the sick and the wounded on board the transports "Olivette" and "Seneca" during their recent trips from Cuba have occasioned this new regulation. Formerly doctors from civil life have been assigned to transports upon which the wounded and sick were carried. The new order of the Surgeon-General relieves them from further duty.

Dr. Wood Military Governor of Santiago.—Dr. Leonard Wood, who, at the beginning of President McKinley's term of service, went to Washington as his family physician, has recently been promoted to be Brigadier-General and Military Governor of Santiago. At the beginning of the war, Dr. Wood enlisted as a volunteer, and went to the front as Colonel of the Rough Riders. It is a source of congratulation to the city of Santiago, as well as to our own Government, that a man possessing such eminent qualifications as a sanitarian, should be appointed to the responsibility of Military Governor at this time.

Investigation of the "Seneca" Incident Surpressed.—It is currently reported that the investigation demanded by Surgeon-General Sternberg into the responsibility for the shameful cruise of the transport "Seneca" is being surpressed. It is certainly to be hoped that this is not true. Such an outcome would be most unfortunate and assuredly a mistake. In a very short time representatives of foreign nations who were on the "Seneca" will reach home, their mouths will be unsealed and then the whole story will come back to this country, and the last state of the parties responsible for any suppression of the truth will be worse than if they had frankly allowed all the facts to be known.

The Marine Hospital Service and National Quarantine.—The advantage of having the quarantine of the country under National control so that the rules may be uniform, and prompt and vigorous measures enforced at all points, is being constantly illustrated during the present war. The fact that the Marine Hospital Service is a department of the General Government has enabled Surgeon-General Wyman to cooperate readily with the Army and Navy Departments in his efforts to prevent the invasion of yellow fever from Cuba. At the present time, there is imminent danger of yellow fever being brought to this country and making its entrance at various ports, from Portsmouth, N. H., where the Spanish prisoners are quartered, throughout the whole extent of the Atlantic and Gulf coast, as far as Galveston, Tex. By the cordial cooperation of the Army, the Navy, and the Marine Hospital Service, in establishing uniform quarantine, the dreaded disease has not, as yet, gained foothold upon our territory.

WILLIAM PEPPER, M.D., LL.D.

OBITUARY.

DR. WILLIAM PEPPER.

Dr. William Pepper of Philadelphia died July 28th at Pleasanton, Alameda County, California, from acute heart failure, the direct result of overwork.

William Pepper, formerly Provost of the University of Pennsylvania and one of the most eminent physicians of the country, was born in Philadelphia on August 21, 1843. He was graduated from the University of Pennsylvania in the class of 1862, and from its Medical Department two years later. Dr. Pepper entered at once the practice of medicine and gained distinguished success in his profession. He was Lecturer on Morbid Anatomy in the university from 1868 to 1870, and on Clinical Medicine from 1870 to 1876, and professor of the latter subject from 1876 to 1887, when he was elected to the Chair of the Theory and Practice of Medicine, to succeed Dr. Alfred Stillé. He continued to hold that chair until his death.

In January, 1881, he was elected Provost of the University. Under his administration the institution developed along modern lines as never before. In 1881 the

Wharton School of Finance and Economy was founded; in 1883 a department of veterinary medicine was added; the foundation of a school of biology and the establishment of a department of physical culture followed in 1884; the school of American history and a department of archeology and paleontology were added in 1891, and the department of hygiene was founded in 1892. These rapid advances were largely due to Dr. Pepper's personal efforts.

Dr. Pepper had one of the largest practices in the country, and he continued to attend to it in addition to guiding and molding the general policy of the university and the development of the numerous constituent schools. He also regularly continued his literary work. He founded *The Medical Times*, and was its editor in 1870 and 1871. His most important work was the editing of "A System of Medicine by American Authors," published in 1885-1886. He was a constant contributor to medical journals, and published many books and pamphlets on medical and scientific subjects.

Dr. Pepper was medical director of the Centennial Exposition in 1876, and for his services received the decoration of Knight Commander of the Order of St. Olaf from the King of Sweden. He was largely instrumental in founding the Pennsylvania Museum and School of Industrial Art. He was a Fellow of the College of Physicians, a member of the American Philosophical Society, President of the American Climatological Society in 1886, and held the same office in the Association of American Physicians in 1891, and was elected first-president of the Pan-American Medical Congress, which met in Washington in 1893. In 1881 he received the degree of LL.D. from Lafayette, and again from Princeton in 1888.

Feeling that his multifarious duties were too great a burden he resigned the provostship of the university at the commencement of 1894. At that time the facts were brought out that not only had Dr. Pepper suffered a loss in his income as a physician by the time given to the university, but also that he had declined to accept any salary as provost. Moreover, he had at that time made contributions to the university amounting to from $20,000 to $30,000 a year. He accompanied his letter of resignation with a gift to the university of $50,000 toward a fund for the extension of the university hospital. During his term as provost the value of the university property rose from $1,000,000 to $5,000,000; its teaching force increased from 88 to 268, and the number of students from 980 to 2180.

CORRESPONDENCE.

THE MEDICAL DEPARTMENT OF THE ARMY —LETTER FROM GEN. STERNBERG.

To the Editor of the MEDICAL NEWS.

DEAR SIR: I regret that the pressure of official duties makes it impossible for me at present to make a full reply to your recent letter of enquiry, or to the strictures published by a leading medical journal, condemning the Medical Department of the Army, without a hearing, upon the reports of newspaper correspondents. I will, however, take time to state a few facts.

The number of medical officers allowed by law is inadequate in times of peace. The total number allowed is one hundred and ninety-two (192). There are at present thirteen (13) vacancies. The administration of the Surgeon-General's Office and the Army Medical Museum requires six (6). Eleven (11) are on duty at Medical Supply Depots and as Chief Surgeons of Military Departments. One (1) is at the Soldier's Home; fifty-six (56) at General Hospitals, on Hospital Ships, and at garrisoned posts. Four (4) have been disabled during the war by sickness. Five (5) are on duty as Chief Surgeons of Army Corps. This leaves ninety-six (96) medical officers available for duty with troops in the field. Of these, thirty-five (35) have been appointed Brigade Surgeons of Volunteers and are distributed among the various Army Corps.

This deficiency in regular medical officers has made it necessary to employ nearly three hundred (300) contract surgeons, and more are being employed every day. Most of these doctors from civil life are doing good service, and many of them are thoroughly well-equipped physicians and surgeons with ample hospital experience; but it has been impossible to make a careful selection owing to the great pressure of business in the Surgeon-General's Office, and the urgency has been so great that it has not been practicable to have Examining Boards to pass upon their qualifications.

General Shafter's army at Tampa was thoroughly well supplied with the necessary medicines, dressings, etc., for field service, but owing to insufficient transportation he left behind at Tampa his reserve medical supplies and Ambulance Corps. Every one who has read the papers knows about the difficulties encountered in landing supplies at Siboney. As is usual under such circumstances, the fighting men with their guns and the rations necessary for their subsistence were first landed and hurried to the front. The "Relief," loaded to her utmost capacity with medical supplies, arrived at Siboney four days after the fight at El Caney. That she was not able to get there sooner was a great disappointment to me, but was no fault of the Medical Department. I asked for a hospital ship in good time, but there was unavoidable delay in securing a suitable vessel and in preparing her for service.

It has not been the expectation of the Medical Department that every wounded man would immediately receive the attention of a surgeon. No modern army makes provision for so large a number of medical officers as this would require. But attached to our Army there is a corps of non-combatants known as the Hospital Corps, which is the organized and authorized Red-Cross Corps of the Army. At the outbreak of the war we had eight hundred Hospital Corps men in service. At present there are more than 4000. These men wear a brassard upon the left arm bearing the Red Cross of the Geneva Convention. We have done our best to instruct them in giving first aid to the wounded, and in a majority of cases a first-aid dressing properly applied by one of

these men is all that is required. All of the surgeons who have come from the front have testified to the remarkable results attained from the prompt application of aseptic dressings by our Hospital Corps men and by the soldiers themselves, or their comrades. The proper application of the dressings contained in the first-aid packet, which is carried by every soldier, is, under existing regulations, a matter in which every enlisted man has special instruction. For some time past this instruction has been given first by our medical officers to the company officers, and by them to the enlisted men.

My position with reference to the inadvisability of sending female nurses to our camps of instruction, or with our armies in the field, has given great offense to some members of the Red-Cross Society, and it is evident that the unjust attacks which have been made upon me, and upon the Medical Department of the Army result largely from the stand I have taken in this matter. I have gladly accepted the assistance offered us in the way of delicacies for the sick, etc., and we have now a large number of trained female nurses on duty at our general hospitals where they are giving great satisfaction, but I see no reason to change my views with reference to the sending of female nurses with our troops in the field. They are an incumbrance to an army mobilized for active operations. This objection does not apply to the sending of immune female nurses for service in our yellow-fever hospitals near Santiago, and I have already sent nearly one hundred.

The first-aid dressing is to be put on at or near the firing line, and the men have usually to be transported to the field hospitals on litters. In this age of aseptic and conservative surgery, comparatively little operating is required, and our regular force is ample to attend to this. Moreover, we have men selected for their experience and skill to decide whether operations are necessary, and to perform them. I have never objected to the surgeons and ambulances of the Red-Cross Society going to the field for the purpose of rendering any necessary assistance, but, in my opinion, they should be independent as regards transportation, and should not call upon the Government for assistance in getting to the field of operations. If there has been any failure to get necessary supplies to Cuba it has been because of the difficulty of securing adequate transportation, and of landing supplies through the surf; but we have been constantly importuned to transport Red-Cross agents and female nurses to the front. I am informed that many of these so-called nurses had never received any special training to fit them for the duties they were so eager to undertake. The National Red-Cross Society should have been entirely independent of Government transportation if it expected to fulfil its proper function of affording aid to the wounded of both armies, in accordance with the terms of the Geneva Convention.

As regards the "Seneca," I am informed by Major Torney, in charge of the hospital ship "Relief," that he transferred forty-two (42) wounded men, most of whom were entirely able to take care of themselves, from the "Relief" to the "Seneca" because at that time it was expected that our troops would storm Santiago, and that a large number of wounded would be sent to the hospital ship for treatment. For the same reason a certain number of convalescents were sent from the shore hospital. Two acting-assistant surgeons were sent on board with a supply of the most necessary medicines and dressings. The wounded who were sent by the "Seneca" were nearly all able to walk and take care of themselves, and required comparatively little attention. The statement that no medical supplies were sent with them is false. No doubt there was some deficiency, and some discomfort upon this overcrowded ship, but the Medical Department is in no way responsible.

Finally, I would say that when the medical officers now at the front return home I expect to have full information with reference to the efficiency of the medical service in the vicinity of Santiago, and in the meantime I hope that the profession at large will not be so ready to draw inferences unfavorable to the Medical Department of the Army on the basis of reports published in the daily papers as the editor of the *Medical Record* has been.

Very respectfully,

GEO. M. STERNBERG,

Surgeon-General, United States Army.

WASHINGTON, D. C., August 2, 1898.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

KOCH ON THE SPREAD OF THE BUBONIC PLAGUE—AN ENDEMIC FOCUS OF THE DISEASE IN UGANDA ON THE SHORES OF VICTORIA NYANZA—NO FURTHER DANGER TO CIVILIZATION FROM PLAGUES—LEYDEN ON HEART-NERVES—THE HEART AS AN INDEPENDENT MUSCULAR AGENT.

BERLIN, July 27, 1898.

PROFESSOR KOCH'S talk before the Berlin branch of the *Deutsche-Gesellschaft für offentliche Gesundheitspflege* (German Society for the Care of Public Health) was the medical feature of the week here, and was attended by some 500 medical men. It was followed by a banquet in honor of the guest of the evening. Truly the Germans know how to honor their distinguished medical men, and do it with most commendable cordiality, without requiring them to have shuffled off this mortal coil before the honors come.

Some decenniums ago, Koch said, the plague seemed to have lost the epidemicity which had so fearfully characterized it in history. We heard of isolated, or even groups of cases in the distant East, but the scourge seemed to have lost its power to spread beyond the limited area where unhygienic surroundings had fostered it into passing virulence. But about five years ago came the rude awakening from this false security into which Europe had been lulled. There came the news of its ravages in India, then it appeared in Persia, finally in 1894 it was reported on the Chinese coast, and as Hong Kong, in whose neighborhood it appeared, is in intimate commercial relations with the civilized world there arose the dread of an invasion. Those who knew something of the history of

this terrible scourge of Europe and Asia in the past feared for the present. Then two years ago it appeared in Bombay, and some cases got to Suez, and even two cases turned up in London, so that fears were not ungrounded.

Study has shown that it is the old plague, and has enabled us to know its characters. Its pathologic anatomy is now known, and Kitasato and Yersin have found its bacterial cause. The study of the disease in rats has at once substantiated the identity of the modern with the antique plague, and confirmed the old tradition with regard to its fatality in these animals. The disease would really seem to be a rat, not a human, disease, attacking these animals, usually so intensely resistent to all disease, on the slightest exposure, and raging among them with the greatest virulence, only attacking men at times when special circumstances have made the virus specially infective.

We have found that, knowing the exact bacteriology of the disease, sanitary regulations will be effective in protecting other countries from invasion. The main interest, then, has centered in the discovery of the places where epidemics originate, for it is clear that there is not a rebirth of the contagium each time that the plague arouses attention, but that it is almost certainly endemic in certain localities, successive cases of it occurring more or less sporadically, and finally leading under favorable circumstances to an epidemic.

Some of the places where plague is endemic are well-known. There is evidently a persistent focus of the disease some place in Mesopotamia between the Tigris and Euphrates Rivers from which some of the earliest epidemics of the plague in history came, but which would seem not to have gone out, even down to our day. The Indian epidemics of the plague would seem to have come from the country lying near the Himalayas, especially in the western part of the Chinese Empire in Thibet. A third plague-spot, in the literal sense of the word, evidently exists south of Mecca on the Arabian shores of the Red Sea from which, through the medium of the Mohammedan pilgrimages, a number of epidemics of plague have been called into existence.

While in German East Africa, Koch found that a fourth focus of plague, a locality in which, according to the natives and missionaries, the disease has been endemic for so long as there is any tradition, exists on the northern shores of Lake Victoria Nyanza in Uganda. His attention was called to the fact by the occurrence in Kisiba, the most northwesterly district of German East Africa, of certain suspicious cases. At his request an army medical man investigated the disease directly in the infected district, and sent the specimens of a number of cases to Koch, on the coast three-month's journey away. The specimens were in excellent condition when they arrived, and Koch came to the absolute conclusion that genuine plague was endemic at least in this part of Central Africa.

From here he thinks that certain epidemics have gone down the valley of the Nile, and so invaded Europe. The otherwise inexplicable epidemic of the disease at Tripoli in the Seventies probably had its origin in some such way as this. This plague-spot is in the progress of civilization gradually becoming not so segregated as it was. Caravans often come from this district, and the English in British East Africa are engaged in building a railroad from the coast into this Victoria Nyanza district of Uganda, which will be completed in two years, and will still further add to the danger of the importation of the disease into Europe.

There is really no need for alarm, however, for knowing the exact bacteriology of the disease as we do, we can be perfectly confident that our sanitary precautions will suffice to prevent invasion. This definite knowledge of the localities from which invasion may be expected will prevent us from being taken by surprise, and modern medical science can look with justifiable self-congratulation upon the advance in medicine which has enabled us to absolutely rule the dread disease which so often devastated Europe.

At a recent meeting of the Society for Internal Medicine, Professor Leyden discussed the question of heart-nerves, and rather surprised his audience, I think, by showing that he has adopted the physiologic opinion which has been gaining ground recently, that the nerve-fibers demonstrable in the heart so plentifully are not motor but sensory, and that the heart-muscle is itself essentially motor, containing in its vital qualities the essential principle of its own activity, and not depending either for initiative or continuance of its action upon its intrinsic nervous mechanism.

This opinion of the automatism of heart-action rests on some very good reasons drawn especially from embryology. The heart beats in the embryo long before any nerve-mechanism or fibers can be demonstrated in it, before any nerve substances has been really differentiated autogenetically. Engelmann, the successor of Du Bois Reymond in the Chair of Physiology here at Berlin, has especially insisted on this. His and Romberg have pointed out that the ganglionic character of the heart-nerves associates them naturally with sensory nerves, and that it is to this class, not the motor-nerves, that the heart-nerves all belong. Hofmann has shown that the removal of the whole septum of the frog's heart with all the ganglia of Remak that it contains does not disturb the heart's contractility or persistent contraction at all. Krehl has even isolated certain parts of the heart in which no ganglia could be demonstrated, and so long as they represented definite anatomic parts of the heart-muscle they could be made to continue their pulsations for hours.

His teaches that the conduction of the contractile wave in the heart is through muscle-fibers not nerve-fibers, and Engelmann has demonstrated by accurate measurements of the time it takes the pulsatile wave of contraction to pass from the sinus through the auricle to the ventricle that this wave is 300 times too slow to come through motor nerves, and so must find its way through the muscle-fibers.

Professor Leyden demonstrated before the Society the results of section of the vagus with irritation, not of the peripheral end, but of the proximal end. The well-known resultant momentary stoppage and slowing of the heart,

which occurs when the proximal as well as the peripheral cut end is irritated, Professor Leyden took to indicate the sensory function of the vagus; the usual explanation that the nervous irritation is communicated to the other vagus in the nervous centers, and then carried down as an inhibitory impulse, seeming far-fetched. In the frog's heart with both vagi cut, irritation of the proximal end still slows the organ.

The acceptance of these views as to the physiologic function of heart-nerves, and the automatism of the heart-muscle, would lead to a change in much of the present clinical consideration of cardiac conditions. Most of the terms used depend on the supposed stimulant and inhibitory functions of nerves. They are not likely to be adopted at present, yet their ever-increasing claims for attention on the part of clinicians is evident. There are some other views of Professor Leyden's on nervous questions in which he was as distinctly unique in his position as this, and yet in which time has shown that he was in advance of his time, and upholding views that have since become the universal teaching in medicine.

TRANSACTIONS OF FOREIGN SOCIETIES

London.

TREATMENT OF CHRONIC BRIGHT'S DISEASE—ACUTE DILATATION OF THE HEART IN RHEUMATIC FEVER —SAGITTAL FONTANELLE AT BIRTH.

AT a meeting of the Royal Medical and Chirurgical Society, June 28th, EWART read a paper on the "Treatment of Chronic Bright's Disease." He pointed out that the methods of treatment hitherto adopted in chronic Bright's disease (tubal nephritis) have not cured the trouble, and often have not removed the symptoms. Still, there are patients who recover spontaneously, even when the disease is of long standing, and this leads to the hope that a suitable treatment may yet be found, inasmuch as the lesions are not necessarily fatally destructive of the structure of the kidney. An uncomplicated tubal nephritis may be looked upon as a long-standing catarrh. Its symptoms are: (1) Dropsy, (2) anemia, (3) oliguria, and (4) cachexia, often concealed by the persistent edema. Edema may be considered Nature's protection against fatal intoxication. In itself edema is harmful by choking the tissues and impeding lymphatic circulation. It hinders nutrition both locally and generally. Its usual treatment by rest in bed impairs the vital functions. Tubal nephritis may, therefore, properly be looked upon as a lymphatic disease, and treated accordingly. The edema should be made to collect in the lower extremities by slanting the bed, and the trunk and upper extremities thus freed from the edema, should be still further improved by massage. Acupuncture or incision and drainage, if faithfully persisted in, will afford relief to the edematous tissues of the whole body, will remove from the system a large amount of contaminated fluid, and will grant the kidney a physiological rest by opening up another exit for the ingested fluids. A surcharge of the blood with alimentary and effete products being thus avoided, a varied diet can be given, to the great benefit of the patient. A free, lymphatic circulation is an essential part of the treatment of the kidney in nephritis. Southey's tubes or small incisions into dilated lymphatics, preferably at the back of the ankles, are the means employed to drain the edema. Every antiseptic precaution should be employed, and the wound kept covered with a cloth moistened with a mild antiseptic solution. The surrounding skin should be smeared with vaselin to prevent the bad effects of constant soaking. While the flow continues free a liberal diet may be given. If it tends to dry up, it may be necessary to resort to a milk diet for a few days until it is again well established. In a recent case the patient will soon be able to leave his bed. The usual methods of medication directed to strengthening the heart will succeed better when the edema has been relieved.

LEES read a paper on "Acute Dilatation of the Heart in Rheumatic Fever," a condition which he claimed is a common thing, even when arthritis and pyrexia are slight in amount, and apart from endocarditis and pericarditis. In support of these propositions he presented tracings of the cardiac dulness made from patients under his care. The accuracy of estimates of cardiac dulness obtained by percussion has been repeatedly confirmed by autopsies. The acute cardiac dilatation in rheumatism is analogous to that seen in influenza, and in both diseases it is the result of the poisonous action of a microbic toxin on the muscle of the heart.

A number of tracings of the hearts of children suffering from rheumatism and chorea were also presented. They showed also, without exception, an increase in the cardiac area in the beginning of the disease, with a decrease as recovery took place. If relapse sets in, there may be a return of the cardiac enlargement. The value of this acute dilatation in the diagnosis of arthritis of doubtful nature was pointed out. the speaker holding that many times symptoms are set down to adherent pericardium in recurrent cases, which are really due to this cardiac increase.

At the Obstetrical Society, July 6th, LEA read a paper on the "Sagittal Fontanelle in the Heads of Children at Birth." Several abnormal fontanelles have been described: the nasofrontal, cerebellar, mediofrontal, and sagittal, but the last named is of especial interest to obstetricians. From the examination of 500 consecutive infants at birth he was able to draw some pretty general conclusions. The fontanelle is situated 2 cm. (4/5 inches) in front of the posterior fontanelle, on a transverse line drawn between the two parietal eminences. Its average length is 1.5 cm., and width 1 cm. It may form a space as large as the anterior fontanelle, and may be present on one or both sides. He found it bilateral in 17 cases, and unilateral in 5 cases. Taking them together, the fontanelle was present in 4.4 per cent. of the cases. The membranous space may be surrounded by well-developed bony edges, or the posterior portion of the parietal bone may be wanting. This fontanelle has a medico-legal as well as obstetrical interest.

HERMAN said that the presence of this fontanelle might mislead one accustomed to rely on the digital examina-

tion of the sutures and fontanelles for the diagnosis of the fetal position. This would not, however, trouble anyone who used abdominal palpation to determine the child's position. A second point is that the presence of the fontanelle, if correctly recognized, might induce one to apply forceps in a case where perforation would otherwise be performed, since it would show that ossification was backward.

SPENCER doubted the so frequent occurrence of a sagittal fontanelle. He thought that perhaps a fissure had in some instances been mistaken for a fontanelle. He had examined the skulls of 300 newborn infants, but had in no case seen a sagittal opening which was at all comparable to the anterior fontanelle.

Edinburgh.

ACUTE AND CHRONIC RHEUMATIC MYOSITIS—THE OPERATIVE TREATMENT OF ENLARGED PROSTATE —THE RELATIVE POSITIONS OF THE PROMONTORY AND THE SYMPHYSIS PUBIS.

MILLER read a paper, entitled "Rheumatic Myositis in its Acute and Chronic Form," before the Medico-Chirurgical Society, June 1st. The affection is often mistaken for articular rheumatism, especially if the muscle involved overlies a joint. The symptoms are pain, swelling, fever, and constitutional disturbance. The pain is situated at the origin and insertion of the muscle, and is increased by its contraction, though not by all of its motions. The effusion into the skin and subcutaneous tissue may cause a crackling on palpation, which is especially well marked in pleurodynia. Acute attacks subside in a few days. In the chronic form of the disease the stiffness is more or less constant, and there is muscular wasting. Points to be noted are: (1) The pain comes on in advance of wet weather; (2) the pain is often associated with a falling barometer, but may occur with a rising barometer if the wind is from the north or east; (3) the pain may subside when the rain has fairly set in; (4) mists cause an attack, as do (5) east winds without mist; (6) pain may be conspicuously absent in cold weather if the air be dry. This is most noticeable in the Arctic regions.

Internally the alkalies are good, as are also the salicylates. Iodid of potash and actea racemosa are also valuable, the latter in lumbago and stiff neck. The best local treatment is the application of dry heat. Rubefacients are also allowed, but blisters are bad for the reason that the pain they cause keeps the limb still, and stiffness of the joint is likely to follow. Massage to give the best results should be both passive and active. Voluntary motions, especially those which so stretch the muscles as to cause pain, are better than any passive motions. Excessive movements are to be forbidden. A dry, warm climate is the best for these chronic cases.

THOMSON read a paper on the "Operative Treatment of Enlarged Prostate." The surgeon has to deal usually with the critical cases of this trouble when the patient has failed in his usual catheterization. The old treatment was to tie in a catheter, or to perform a careful catheterization two or three times a day. More recent methods of relief are perineal and suprapubic drainage, but these are at best not cures. The operations available for a cure are: (1) Destruction of the prostatic tissue by a galvanocautery. Bottini, the inventor of this method of treatment, has performed the operation eighty times with only two deaths, but owing to the uncertainty of such blind cauterization the method has not been widely adopted. (2) Suprapubic prostatectomy is an ideal operation in those cases in which the middle lobe of the prostate is especially enlarged. (3) Double castration had been performed by the reader four times, and in every case the result was gratifying. In all cases there was, in addition to the local improvement, an improvement in the general health of the patient. (4) Vasectomy, an operation performed in one case by Thomson, but without affording relief. The conclusions drawn were that prostatectomy is to be performed in all suitable cases, as it is the one effective and comparatively safe operation. In other and unsuitable cases double castration is indicated.

At a meeting of the Obstetrical Society, June 22d, BARBOUR spoke of the position of the promontory as shown by frozen sections made in eighteen different subjects. He found a great variation in both the anatomic and obstetric conjugates, the former varying from 3.8 to 5.6 inches, and the latter from 3.4 to 5.3 inches. The perpendicular height of the promontory above the symphysis varied from 2.4 to 5 inches. In other words, in three-fourths of the cases the whole of the sacrum and a small portion of the coccyx were above the level of the symphysis. The angle between a line from the promontory to the symphysis and a horizontal line from the symphysis varied from 33° to 65°.

SOCIETY PROCEEDINGS.

AMERICAN OTOLOGICAL SOCIETY.

Thirty-first Annual Meeting, Held at New London, Conn., July 19, 1898.

DR. ARTHUR MATHEWSON of Brooklyn in the Chair.

REPORT OF A CASE OF DOUBLE MASTOID DISEASE PRESENTING SYMPTOMS OF AN INTRACRANIAL COMPLICATION; OPERATION; RECOVERY,

was the title of the first paper, read by DR. GORHAM BACON of New York. He said the double mastoiditis followed a severe cold in the head and presented symptoms that led to the expectation of finding sinus thrombosis. The mastoid process on each side was opened and cleansed of granulation material, etc. Neither sinus was opened, as notwithstanding the anterior walls of each were affected, it could not be demonstrated that there was a thrombus. Examination of the pus showed the presence of pneumococci and staphylococci. The patient made a good recovery. The speaker opposed the practice of puncturing the sinus because he does not believe it determines the presence or absence of the thrombus, and because it increases the danger of introducing infection into a healthy sinus.

THREE CASES OF SUPPURATION OF THE LABYRINTH, TWO OF THEM PRODUCING ABSCESSES OF THE CEREBELLUM,

was read by DR. J. ORNE GREEN of Boston. He exhibited the temporal bones in which the labyrinthine structures had been more or less destroyed.

BLOOD-CLOT IN MASTOID OPERATIONS,

was the title of the next paper, by DR. C. J. BLAKE of Boston. He suggested that in cases of acute suppurative disease of the mastoid, after thorough evacuation of the mastoid contents the cavity should be allowed to fill with fresh blood and the wound in the skin be apposed without sutures. This had been done in a number of his cases and the shortest period between operation and complete healing was only four days, while the average period in the successful cases was ten days. The same method was applied to a number of chronic suppurative cases with very good results. The method has the advantage that even if not successful and the part becomes infected the wound can be opened at the first dressing and can then be packed as usual without any damage having been done.

Dr. Blake also read a paper, entitled

CONTROL OF HEMORRHAGE FROM THE SINUS AND MENINGEAL VESSELS DURING MASTOID OPERATION BY MEANS OF INTRACRANIAL PRESSURE.

He described the method which he had adopted some time ago for the control of hemorrhage from the lateral sinus. When by accident or design he opens the sinus and hemorrhage occurs he does not pack the wound but by the use of the spoon curette he proceeds rapidly to increase the size of the bony opening by cutting away its edges, so that the pressure from within the cranium brings the brain substance into the opening and forces the inner wall of the vessel to plug its own lumen. This method possesses advantages over packing in that it is easily and quickly done, promptly arrests bleeding, and causes no delay in finishing the operation on the mastoid.

THE FUNCTIONAL EXAMINATION OF THE EAR, WITH DEMONSTRATION OF BEZOLD'S CONTINUOUS-TONE SERIES,

was contributed by DR. HERMAN KNAPP of New York. He exhibited Bezold's continuous-tone series, ranging from a low fork of sixteen vibrations a second to the higher note of the whistle, about forty vibrations. He also reviewed the methods of functional examination of hearing and laid stress upon its importance, especially with reference to deaf-mutes. Regarding the latter, he cited Bezold's work to show that much can be gained in the education of these people by definitely measuring their hearing rests and shaping the plan of education in accordance with the results. Bezold has proved that the aptitude of deaf-mutes to learn depends upon the tone-rests preserved in their organs of hearing.

TREPHINING OF THE STAPEDIAL FOOT-PLATE FOR OTITIS MEDIA SCLEROSA,

was read by DR. H. A. ALDERTON of Brooklyn. He reported an interesting case in which after all other treatment had been tried and the crura of the stapes had been broken off in an effort to remove this bone he trephined the foot-plate. From his experience he concluded that nothing permanent is gained by the operation, and that while nothing disastrous is to be looked for as the result of it he would counsel against it.

The next paper,

A REPORT OF CASES OF OTOMYCOSIS TREATED BY INSUFFLATION OF BORACIC ACID AND OXID OF ZINC,

was read by DR. SAMUEL THEOBALD of Baltimore. He stated that seventeen years ago, in the *American Journal of Otology*, he had first called attention to this method which he has since used with uniformly good results. He thinks that treatment of such cases by the use of alcohol should be abandoned, as it is not a suitable agent to pour into an inflamed and painful ear, and must be used for a long period of time, whereas, in the method suggested but two or three applications are necessary.

THE SEQUELÆ OF MIDDLE-EAR SUPPURATION, WITH A REPORT OF CASES,

was read by DR. E. B. DENCH of New York. He urged the necessity for removing all the diseased bone in every case of suppurative otitis media in order to protect the patient from infection. He showed that in some cases in which the drainage is free the danger of infection of the brain substance or membranes is less than when the escape of pus is not free from the external auditory canal, although as long as the middle-ear is the seat of inflammatory trouble extension to the cranial cavity through the bony walls is always a possibility.

DOES TYMPANOTOMY AND REMOVAL OF THE INCUS ARREST PROGRESSIVE HARDNESS OF HEARING?

was the title of a paper by DR. C. H. BURNETT of Philadelphia. He said that this question is answered in the affirmative, and sixty-one cases in which the operation has been performed have been reported. In some of these cases the disease has not only been arrested, but the hearing improved, and he thought the time has come not only to make use of the operation in those cases where deafness is advanced to a great degree but to treat the patients while the disease is in its earlier stages and thus avoid greater deafness.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Thirty-fourth Annual Meeting, Held at New London, Conn., July 20 and 21, 1898.

DR. GEORGE C. HARLAN of Philadelphia in the Chair.

The first paper, entitled

WHY THE PROPORTION OF BLIND IN THE COUNTRY IS GREATER THAN IN LARGE CITIES,

was read by DR. LUCIEN HOWE of Buffalo. He said that in the twenty-five largest cities of the United States the proportion of the blind is, with two exceptions, smaller than in the States in which these cities are situated, or taking all the cities of more than 50,000 inhabitants together about thirty-three per cent. less blind are found in

them than the average for the entire country. When the different factors in the production of blindness are examined, whether congenital or acquired, or, under the latter class, whether due to traumatism, general disease, or to local disease, these factors are all practically the same, or are made equal in city and country, with one exception, namely, ophthalmia of infancy.

A rather extended inquiry concerning the habitual practice of physicians in country almhouses, in hospitals and elsewhere in the State of New York indicates that more attention is given to guarding against ophthalmia of infancy in the cities than in the country. The tendency to the habitual neglect of prophylaxis tends to make a rapid difference in the distribution of the blind, estimated at possibly 14 to 1. It is at least the most apparent cause of this difference and probably accounts for the greater part of it. It follows from this apparently warrantable conclusion that if as great care were taken in general throughout the country as is given on the average in the cities to prophylaxis the number of blind in the United States would be decreased in a single generation by several thousands.

SOME UNUSUAL TUMORS OF THE EYE AND ORBIT

was the title of the next paper, read by DR. CHARLES STEDMAN BULL of New York. He reported one case of sarcoma, which was supposed to be due to an injury of the eye received at some previous time, and a second case in which the microscopic examination showed the appearance of tubercles, but in which the clinical history of tuberculosis was negative.

DR. E. FRIDENBERG of New York then read a paper on

OSTEOMA OF THE ORBIT WITH ENOPHTHALMUS.

The two features of interest in this case were, first, the position of the tumor, which was located much more toward the temporal aspect of the orbit than usual, the mass of the osteoma being about at the center of the upper orbital margin, and, secondly, the position of the eye, which was crowded backward into the orbit and slightly downward; in other words, there was enophthalmus instead of the customary exophthalmus. The tumor with the anterior wall of the sinus was chiseled away and the patient made a good recovery, though the eye remains still slightly lower than its fellow. Vision of 22/100 was improved to 20/50 by the use of glasses, the Javal ophthalmometer showing the presence of 8D astigmatism, which was corrected by +4.Cyl. ax. 90°○-4.Cyl. ax. 180°.

ABSCESS INVOLVING THE FRONTAL SINUS, WITH DESTRUCTION OF THE VAULT OF THE ORBIT AND DEPRESSION OF THE EYEBALL

was the subject of a paper by DR. C. F. CLARK of Columbus. This abscess seemed to occur as the result of traumatism, the patient having received a blow in the face about a year previously, and having suffered more or less constantly from headaches and other symptoms which might be attributed to abscess in the sinus. The bone had been eroded to such an extent that the brain cavity was invaded, and the depression of the eye was sufficient to porduce a hyperphoria of the opposite side equal to 5½°. The patient did well after operation, but the wound has not thoroughly healed, probably because of the presence of some sequestra. During the year before she came for treatment she would occasionally have attacks of pain followed by discharge of mucus and pus from the nose and mouth and she noticed at such times that the size of the swelling of the orbit diminished. Pressure over the swelling met with such firm resistance that it was at first suspected that the condition was produced by an osteosarcoma.

A LARGE TUMOR OF THE ORBIT (FIBROSARCOMA) OF TWENTY-THREE-YEARS' STANDING; REMOVAL,

was reported by DR. F. M. WILSON of Bridgeport, Conn. He exhibited the specimen, which was of immense size for an orbital tumor. The patient had had the power of opening the lids but could not close them over the tumor except by taking hold of the free border of the upper lid and pulling it out. The tumor had existed for a remarkably long time and there were conflicting opinions as to the advisability of operation. Up to the present time it appears to have been a success. Although the eye was so displaced that the cornea was 1¼ inches in front of the orbit, motility of the iris and some vision has been retained.

A CASE OF LIPOMA OF THE ORBIT

was reported by DR. EMIL GRUENING of New York. It occurred in a young man, was lobulated, about the size of a lima bean, and microscopic examination showed nothing but fat-cells. The author stated that most tumors of this class which have been reported were subconjunctival tumors.

The next paper, entitled

THE TREATMENT OF ENTROPION OF THE LOWER LID WITH CAUSTIC POTASH,

was read by DR. SAMUEL THEOBALD of Baltimore. He said that in applying this method the aim should be to produce an eschar 3 to 4 mm. wide, parallel with the lid margin and extending the whole length of the tarsus. The action of the caustic should not be allowed to approach nearer the edge of the lid than 1½ to 2 mm. When the requisite effect has been produced the caustic action should be checked by the application of vinegar diluted with an equal quantity of water, or a solution of acetic acid of about the same strength. The eschar soon begins to contract and the lid, which up to this time has been held in an everted position, no longer shows an inclination to turn in. It is seldom necessary to repeat the operation, but this can be done if necessary. The treatment is especially applicable to senile entropion, but useful also in other varieties. Better results, it was thought, could be obtained by the use of the caustic than by the knife and no other anesthesia is necessary than the local application, on cotton, of cocain.

LYMPHOMA OF THE LIDS

was the title of the next paper, which was read by DR. MYLES STANDISH of Boston. He reported a lymphomatous growth in the lower lid close to, but not involving, the lachrymal sac. The administration of arsenic had resulted in its cure.

A CASE OF SPINDLE-CELL SARCOMA INVOLVING THE CONJUNCTIVA AND CORNEA; REMOVAL OF THE GROWTH WITHOUT IMPAIRMENT OF SIGHT,

was reported by Dr. S. B. St. John of Hartford. The patient was a man seventy-two years of age who had lost the right eye twelve years previously as the result of traumatism. The growth appeared upon the left eye and grew in 2½ months from the size of a pin-head to that of a large pea. It sprang from the conjunctiva, was movable with that tissue, and overlapped the cornea. It was removed much after the fashion of that employed in a pterygium operation.

CONJUNCTIVAL MELANOSARCOMA INVOLVING THE CORNEA

was reported by Drs. John Green and A. E. Ewing of St. Louis. The tumor was a true melanosarcoma, involving the cornea to such an extent, and was of such a size, that it became necessary to enucleate the eye.

Drs. Green and Ewing also reported a case of

HYPOPION KERATITIS AND BREAK IN DESCEMET'S MEMBRANE,

in which, preceding perforation, fluorescin was passed through the ulcer into the anterior chamber. The hypopion, 5 mm. in height, occurred as a sequence of a traumatic ulcer of the cornea. The treatment which Dr. Ewing followed with good results was the free use of hydrogen-peroxid solution of normal strength, applied on a little mop to the surface of the ulcer and held there, and the application renewed half a dozen times until there was a cessation of the ebulition. On making this application bubbles of gas would appear in the anterior chamber, but the gas was rapidly absorbed and in a few hours nothing remained of it. Fluorescin produced its characteristic reaction. The hydrogen peroxid seemed to have the effect of breaking up the hypopion mass and producing the good results that occurred. The conclusions drawn by the essayist were that one source of hypopion keratitis is through a direct break in Descemet's membrane, by exudation from the iris, or, possibly, from the epithelium of Descemet's membrane.

A case of interstitial keratitis, congenital in origin, was reported by Dr. H. F. Hansell of Philadelphia. The patient was first seen when only thirty-six hours old, and presented these symptoms: A thin, watery discharge from the eyes, lids slightly swollen and bluish-red in color, and conjunctivæ smooth, but the ocular portion distended from the fornix to the limbus of the cornea by an almost transparent effusion. The cornea showed on inspection a gray infiltration of the deep layers, consisting of fine points that tended to become confluent, most dense over the pupil, without vascularity or loss of epithelium. The child was poorly nourished, probably because of the fact that the mother, though ordinarily a healthy woman, had been in bad health throughout her pregnancy. There was no history of specific disease. The child was given tonics, and at the end of six weeks there remained only a slight opacity of the cornea. The local treatment consisted of applications of mydriatics. A similar case was referred to, reported by Barnacheff, in which the cornea became entirely clear.

The next paper, on

A NEW TREATMENT OF ULCERS AND OTHER INFECTIOUS DISEASES OF THE EYE BY CASSAREEP,

was read by Dr. S. D. Risley of Philadelphia.

This preparation is made from the juice of the black cassava, and is used in the form of a ten-per-cent. ointment. It is applied freely between the lids, and the eye subjected to massage to distribute it, and in the corneal cases, the protecting bandage applied. It causes no irritation, and rapidly brings about improvement.

The first paper read during the afternoon session was by Dr. J. P. Worrell of Terra Haute, Ind., entitled

SPONTANEOUS EXPULSION OF A FOREIGN BODY FROM THE ANTERIOR CHAMBER.

The patient was a boy who had received an injury of the right eye while exploding a gun-cap by striking it with a hammer. After the inflammation had cleared up a small piece of bright metal could be seen on the inner surface of the cornea. The patient declined operation for its removal, and some days later appeared with the statement that "feeling something scratching the eye, he rubbed it with a bit of cotton, and removed, with some secretion, a small piece of bright copper." No inflammatory trouble followed.

SOME OF THE EARLIER SYMPTOMS OF SENILE CATARACT

was the title of the next paper, read by Dr. W. F. Mittendorf of New York. The essayist had carefully observed the last 508 cases of incipient senile cataract which had occurred in his practice in order to determine the exact location of the first changes in the transparency of the lens. Of these, 106 were central and 402 peripheral, and of the latter the starting-point of the striæ was found in the upper periphery in 13 cases only, in the outer periphery in 47, in the general pheriphery, 48, and in the greatest number, 286 cases, in the lower and inner quadrant. Admitting that cataractous changes do not depend upon senility alone, but more particularly upon the nutrition of the lens, Dr. Mittendorf offered as a possible reason for the great prevalence of opacities in the lower inner quadrant the theory that there is a constant accommodation for small objects, especially in the reading by artificial light, requiring a more or less forced convergence and a downward look, during which the pressure upon the surrounding tissues is an impediment to the nutrition of this particular portion of the lens.

THE OPERATIONS FOR SECONDARY CATARACT

was read by Dr. H. Knapp of New York. He reported a very interesting case of secondary cataract operations. The primary operation for removal of the cataract was without special interest. The capsule becoming cloudy and necessitating a secondary operation, it was needled in the ordinary way. The immediate result was good, but two days later reaction occurred, and a severe, acute glaucoma set in. An iridectomy was at once attempted, but it was found impossible to catch

hold of the iris, so the operation was abandoned. The patient was relieved, however, of all pain and discomfort as a result of the paracentesis, and remained so for four days, when the trouble again set in. A second attempt at iridectomy was made, and this time successfully. The relief was permanent. Dr. Knapp then presented a tabulated report of 70 cases of secondary cataract operated upon since October, 1897. Sight was improved in 63 instances, remained the same in 6, and was almost lost in 1. Two cases besides the one quoted above were complicated by glaucoma, one of them being relieved by myotics and the other by an iridectomy.

Considering the advisability of operating in subjects having vision not below 20/70, the author said it must depend upon the case, but that ordinarily he believed one should attempt to give the patient the best sight his eye is capable of, especially as the secondary operation is safe. He considered discission the proper operation, and laid down as a rule of paramount importance, "Cut, don't tear." As the region of the wound made in the primary extraction is the weak point in these eyes, he considered it advisable to avoid that region as much as possible in the secondary operation, and to make a T-shaped incision in the capsule, the horizontal arm of the T being situated below the linear scar.

DELAYED UNION AFTER CATARACT EXTRACTION

was the title of a paper by DR. GEORGE C. HARLAN of Philadelphia. He reported two instances of delayed union after cataract operations, in one of which union took place some where between the tenth and seventeenth days, and in the other at the end of 20 days. By a review of the literature he had found 26 similar cases in which the delay had lasted from 5 to 20 days. In 20 of these cases no cause could be given for the wounds having remained open. He stated that such cases seem to require no special treatment other than the application of atropin and a slight pressure-bandage, together with treatment of any complications which may arise.

SECOND DAY—JULY 21ST.

The first paper, entitled

PROTARGOL IN THE ANTISEPTIC PREPARATION OF THE CONJUNCTIVA PRIOR TO CUTTING OPERATIONS ON THE EYEBALL,

was read by DR. B. E. FRYER of Kansas City, Mo. He uses a two-per-cent. solution of protargal as an antiseptic, and finds it preferable to solutions of mercuric bichlorid, etc. It is destructive to all organisms and is not irritating.

BUPHTHALMIA, AN INTERESTING SERIES OF CASES OCCURRING IN THE SAME FAMILY,

was read by DR. WALTER B. JOHNSON of Paterson, N. J. Three children in one family were found buphthalmic within the first few years of life. Ophthalmic examinations were not satisfactory. Two of the children were operated upon in Naples, and the third by the speaker. In every case the progress of the disease was arrested. The mother's eyes were normal, but the father thought he had never seen out of one eye, in which a disintegrated calcareous lens prevented a fundus examination.

A CONTRIBUTION TO THE PATHOLOGY OF THE EYE AND ITS APPENDAGES

was read by DR. G. E. DE SCHWEINITZ of Philadelphia. He reported the following cases:

CASE I.—Primary carcinoma of the caruncle. A small growth entirely replacing the right caruncle, about the size of an ordinary pea, which had existed for a number of years. Microscopic examination proved it to be carcinomatous. So far as known there has been no recurrence.

CASE II.—Prelachrymal growth with the histologic characters of tubercle. A small tumor anterior to the lachrymal sac was discovered while probing the tear-duct. It was easily removed, and on examination showed the appearances of tubercle, although no tubercle bacilli could be found.

CASE III.—Angioma of the lachrymal gland extending to the apex of the orbit; removal, with preservation of the globe; functions of the eyeball and of the external ocular muscles, with the exception of the levator, which was involved in the growth. This tumor, which is exceedingly rare, consisted of an angiomatous growth involving the lachrymal gland, and extended deep into the orbit. It was probably congenital. In front of the ear, on the same side, there was a small cavernous angioma about one and one-half inches in length, and one inch in width, but not communicating with the growth of the lid.

The next paper, entitled

REMARKS ON CASES OF HIGH MYOPIA; TREATMENT OF ONE CASE BY REMOVAL OF THE CRYSTALLINE LENS,

was read by DR. H. D. NOYES of New York. He said that the interesting features of this case were the early occurrence of converging squint, the rapid development of myopia between the sixth and eighth year, the removal of the lens produced a change of 16D, and with it an improvement of vision to double the previous condition; binocular vision was not secured by the refractive changes, and diplopia was never observed.

CONTRIBUTION TO THE OPERATIVE TREATMENT OF HIGH MYOPIA, WITH REPORT OF AN ADDITIONAL CASE,

was read by DR. W. H. WILMER of Washington. The operation in the case reported decreased the myopia by 22.5D., and the vision was double what it had been before operating. In regard to the mode of operation, the author preferred a slight discission, making a very small opening in the anterior capsule, followed by extraction within six days. As to the amount of myopia which offers the best operative result, he considered the ideal case to be the one in which two or three diopters of myopia would remain after the operation. According to his experience, this would mean a myopia of twenty-five diopters.

THE PATHOLOGY OF EXPERIMENTAL QUININ AMBLYOPIA

was read by DR. WARD A. HOLDEN of New York. His

experiments were made with the aid of the newer stains for nerve-tissues, and he exhibited drawings showing the changes that exist at various stages of the quinin-poisoning. The first changes were shown in the breaking down of the ganglionic cell bodies and a deposition of myalin-like substance in the nerve-fibers. This appeared within three days after administration of toxic doses. From that time until the seventeenth day more ganglion cells were destroyed and at that time changes in the optic nerve, consisting of a breaking down of the medullary sheaths of the fibers, were noticed. By the forty-second day the ganglion cells and the nerve-fiber layer had almost entirely disappeared and the degeneration could be traced up to the external geniculate body and pulvinar. No signs of degeneration could be found elsewhere in the brain or cord.

TWO CASES OF PREMATURE DELIVERY TO PRESERVE SIGHT

was read by Dr. A. E. Adams of Newburg, N. Y. He reported two cases of albuminuric neuroretinitis occurring in pregnant women, with vision reduced to a very low point. Shortly after premature delivery the vision showed marked improvement and the author concluded that if abortion is ever justifiable it is in these cases, especially as the uremic condition of the blood is dangerous to the life of the fetus as well as a menace to the mother.

IMPLANTATION OF SPONGE IN THE ORBIT AFTER ENUCLEATION

was the title of a paper by Dr. S. D. Risley of Philadelphia. In the case reported a fragment of surgeon's sponge, carefully sterilized, was pared down to a size just sufficient to loosely fill the cavity left by the removal of the ball and to permit the suturing of the conjunctiva and the subjunctival tissue over it without undue tension. The design was to furnish a framework for the deposition of connective tissue in the orbit and thus avoid the concaved socket which follows enucleation, and always permits the accumulation of tears and mucus behind the artificial eye. After the operation the appearance was much the same as that presented after the insertion of a glass globe, as in Mule's operation. Two or three months is required to complete the process of absorption of the sponge and the deposition of new tissue.

Dr. C. J. Kipp of Newark, N. J., then exhibited a pair of chalazion forceps, one blade of which was solid while the other contained a slit, so that when this blade is placed over the conjunctival surface of the chalazeon the latter may be incised through the slit and its contents squeezed out by pressure.

The following were elected to membership: Drs. J. W. Ingalls of Brooklyn, Anton Coe of Washington, J. H. Claiborne and F. N. Lewis of New York, J. T. Carpenter, Jr., James Thorington, W. C. Posey, C. L. Veasy, A. G. Thomson, and T. B. Schneideman of Philadelphia, and W. L. Wood of Portland, Oregon.

The officers elected for the ensuing year were the following: President, O. F. Wadsworth of Boston; vice-president, Charles Stedman Bull of New York; corresponding secretary, J. S. Prout of Brooklyn; recording secretary and treasurer, S. B. St. John of Hartford. New London, Conn., was chosen as the next place of meeting.

REVIEWS.

The Peritoneum. By Byron Robinson, M.D. Part I. Histology and Physiology. Illustrated Chicago: The W. T. Keene Co.

The author presents in this volume the results of his original investigations on the histology and physiology of the peritoneum. The histologic work is enormous in extent, and covers experiments made upon various animals, and a minute study of the tissue in man and lower animals. In his conclusions as to the purpose of the subperitoneal tissue, the author states his belief that the diaphragm is the characteristic muscle of mammalian life, in which we think he will find himself at variance with some other observers of note. He has found that the central tendon absorbs as well in the dead animal as in the living, and therefore doubts the so-called "vital" process of endothelial cells, The author brings out clearly that it is through the lymphatics and not through the blood-vessels that absorption takes place in the subperitoneal tissue. Numberless other points that deal with the histology of the peritoneum are brought out, but lack of space prevents the exhaustive review of them which they deserve.

In his study of the physiology of the peritoneum, Dr. Robinson found, as did Adler and Meltzer, that fluids are absorbed from the peritoneum after death. He points out that the areas of active absorption are the most dangerous zones of peritonitis, which is of itself a life-saving inflammatory process; that the peritoneum heals easily and readily; that the peritoneum is inherent with power to resist trauma and infection; that the visceral layer is more sensitive than the parietal and that through many ages of evolution the pelvic, appendicular and large intestinal peritoneal coverings have become more resistant to infectious germs than other regions.

The book is an interesting one and represents an immense amount of toil and perseverance. As an original study, it will command attention and it deserves it. We regret that we can not review it more extensively. A large bibliography is appended. The book is only fairly printed and the proof-reading is not good.

Die Technik der Speciellen Therapie. Von Dr. F. Gumprecht, Privat-docent in Jena. Jena: Gustav Fischer, 1898.

For the practitioner who is at sea in regard to a therapeutic procedure which he would like to try, and for the student who wishes to learn how to carry out such measures this book fills a peculiar place. The procedures carried out for curative purposes in all parts of the body are described in detail, even to the minutest particular. The dangers and complications of each measure are also clearly pointed out. Among the procedures described are intubation, the passing of esophageal sounds, gastric lavage, massage, enemata, thora-

centesis, abdominal puncture, lumbar puncture, catheterization, venesection, transfusion and vaccination. But a few of the details of the book have been chosen in order to convey a notion of the vast field it covers. It is unique and useful, and we should like to see it rendered into English.

DIABETES MELLITUS AND ITS TREATMENT. By R. T. WILLIAMSON, M.D. (Lond.), M.R.C.P., Medical Registrar, Manchester Royal Infirmary. Illustrated. New York: The Macmillan Co., 1898.

THE study of diabetes which formed the basis of the author's discovery of the discoloration of methylene blue by blood taken from a diabetic subject, have made his name well known in connection with this disease. A contribution from his pen in the form of a monograph upon diabetes is bound to be interesting. In the work before us we find a more thorough consideration of the subject than has yet appeared in the English language.

The author, aware of the lack of uniformity of pathologic findings in persons dead of diabetes, devotes but a short chapter to the various theories that are accepted in different parts of the medical world as to the pathologic basis of the disease. The views of Kaufmann, Pavy, Ebstein, Leegen, and Burge are given. The relations between lesions in the pancreas and in the medulla oblongata and a glycosuria are discussed in minute detail, the author holding that these lesions represent complications rather than etiologic power. The chapters devoted to symptomatology and complications are particularly full and thorough. The treatment of the disease is excellently handled, and closes the work in a thoroughly practical manner. The bibliography attached to each chapter and an appendix on diabetic dietetics add value to a work which in completeness and didactic worth is unexcelled. The book-making is excellent.

THE SURGICAL COMPLICATIONS AND SEQUELS OF TYPHOID FEVER. By WILLIAM W. KEEN, M.D., LL.D., Professor of the Principles of Surgery and of Clinical Surgery in the Jefferson Medical College, Philadelphia. Philadelphia: W. B. Saunders, 1898.

THE author has given us a very unique monograph and pioneer in its field, based upon 1700 cases of typhoid complications largely from his own experience and those recorded in literature within the last fifty years. Following the introduction and a short discourse on the pathology of typhoid fever, the book proper opens in Chapter III. with "Typhoid Gangrene," the modified Shattuck lecture for 1896. The closing chapter on "Ocular Complications" is contributed by Dr. George E. de Schweinitz. Appended is the "Taver Lecture," by the author, on "The Surgical Complications and Sequelæ of the Continued Fevers."

The author repeatedly reports many a case as of doubtful origin when it is not confirmed by the demonstration of typhoid bacilli, and particularly those cases antedating the discovery of Eberth's bacillus. Such an array of cases, so critically considered, is well worthy the careful study of the physician and surgeon. To both alike it will open up a new field in the diagnosis of many heretofore neglected complications following in the wake of typhoid fever. The surgeon will find encouragement in the author's conclusions as to the propriety of operating in cases of biliary and intestinal perforations. This work will at all times be authoritative on this subject.

THE RETROSPECT OF MEDICINE. Edited by JAMES BRAITHWAITE, Obstetric Physician and Surgeon to Leed's General Infirmary, etc. Vol. CXVI. London: Simpkin, Marshall, Hamilton, Kent, & Co., Ltd., 1898.

IT is scarcely necessary to do more than to announce the present volume of Dr. Braithwaite's famous "Retrospect of Medicine." The present one is fully up to its predecessors and is complete in its various divisions. Little of importance has been omitted, and the progress of the six months with which the volume deals is fully told.

STUDIES FROM THE DEPARTMENT OF PATHOLOGY OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THIS is a collection of reprints of articles and papers representing the work done during the past year in the laboratory of the College of Physicians and Surgeons. Most of the articles have appeared in the current medical press. Among those of particular interest are: "A Contribution to the Study of Acute Ascending Paralysis," by Drs. Pearce Bailey and James Ewing; a paper on the "Morphological and Biological Examination of Exudates in Cases of Chronic Urethritis," by Dr. Henry Heiman; "Bacterial and Allied Diseases as Applied to the Clinical Diagnosis of Typhoid Fever," by Dr. John S. Ely, and "The Lymphatic Constitution in Its Relation to Some Forms of Sudden Death," by Dr. James Ewing. It is to be hoped that the Director of the Pathological Institute will more frequently submit the work of the laboratory to the public.

THERAPEUTIC HINTS.

The Treatment of Cancer by Application of Arsenious Acid may be rendered painless by adding to the acid an equal amount of orthoform.

For Nausea and Vomiting after Anesthesia.—Saturate a towel with fresh, strong cider-vinegar, and hold or suspend it a few inches above the patient's face. Begin the treatment as soon as the anesthetic is discontinued, and continue it for several hours. Not only is nausea thus prevented, but thirst is also relieved, and the patient is refreshed by inhalation of the vinegar. No ill effects can follow.

For Metrorrhagia.—

℞	Ext. cannabis indicæ	℥ ss
	Ext. opii	gr. 1⅔
	Tinct. capsici	℥ ss
	Rum	℥ i
	Syr. acaciæ	℥ iv.

M. Sig. A tablespoonful every hour until the flow ceases.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIII. NEW YORK, SATURDAY, AUGUST 13, 1898. NO. 7.

ORIGINAL ARTICLES.

WHAT THE PEOPLE OF IOWA EAT.*

BY J. FRED. CLARK, M.D.,
OF FAIRFIELD, IOWA.

A MEDICAL student at graduation knows the dose of potassium iodid or of sodium salicylate and something of the conditions indicating their use as remedies, but when in practice, the doctor's prescription is written, and the patient just before leaving his office asks: "Does it make any difference what I eat?" the young physician is usually at a loss for an answer. His teaching on this point has been meager and his ideas are confused. He doubtless prescribes "a light and easily digestible diet." Again, when detained in the country, the doctor is fed at several meals on fried pork, fried potatoes, heavy bread, and coffee boiled several hours, and before leaving is asked by the man of the house for a little medicine for "stomach trouble," the physician is apt, if a thinker, to see small chance for a few grains of pepsin or creosote to cope with such cooked messes as this farmer must three times a day do battle with. These questions, the prescribing of a proper diet in health and disease and the overcoming of a quite prevalent poor cookery, daily confront the country doctor, and would seem of sufficient importance to be worthy the consideration of this learned Society.

Instruction in dietetics is lacking in our schools, and the advice in our reference-books is, as a rule, inadequate. This is necessarily so because little attention has been given to the subject in the United States until within the last decade. Not until 1880 was any systematic analysis of human food-stuffs made in this country,[1] and not until 1895[2] was any comprehensive American work on dietetics published for our use. The study of cookery, too, is of importance. "Quite as much depends on the suitable preparation of food as upon the selection and limitation of the food itself."[3] The proper cooking of food in Iowa is rare.

In order to obtain some practical information as to what the people of Iowa eat, how their food is cooked, and the relation of the food to the general health, printed question-sheets were sent to a large number of the people of Jefferson County asking for details on this subject. This paper is an attempt to formulate the results of this inquiry, and of several years of personal observation among the people of this county. The answers to the questions were, of course, not scientifically exact, but it is believed a view of sufficient definiteness is obtained to be of some use to our labors for better health.

Jefferson County is a tract of rich farm land in Southeastern Iowa. The county contains one town of 4500 inhabitants, and several small villages. A large proportion of the people are farmers, with the mechanics, merchants, and professional men common to such a community. Of the 17,000 inhabitants, but 75 outside of the county poorhouse have public help to food, and this help is but for part of the year. On the other hand, there is no extreme wealth, the equality in the condition of the people and the freedom from class division being perhaps as marked as anywhere in the world. The mean summer temperature is 71.6° F. The mean winter temperature is 20.6° F., and the mean annual rainfall is 34.33 inches.[4] The grains, fruits, and vegetables common to Iowa are raised in abundance. Pork, beef, mutton, and poultry are produced in excess of the local needs. Wood and coal are easily obtained. With these advantages the choice of a diet by these people would seem easy to all, and with the proper selection of food and good cookery the general health (in so far as it pertains to diet) should be excellent.

A review of the answers on the question-sheets sent to the people show the following prevalent conditions as to food and cooking: The people of Jefferson County eat three meals a day, taking breakfast at 6 to 8 o'clock, dinner at noon, and supper at 6 to 7 o'clock P.M. The principal meal is at noon. It is a general custom on Sunday when, because of rest, less food is needed, to have a much more elaborate dinner. It is also common to have the Sunday meals at widely varying hours, thus disturbing the otherwise regular habits.

Meat is eaten nearly universally three times a day. In the country this meat is usually pork in the summer and pork and beef in the winter. In the towns beef is more generally used. Mutton and poultry give occasional variety to the proteid diet. The percentages of these meats used was not accurately determined, but probably corresponds very nearly with those found by Gibson in his Missouri studies.[5] This meat is usually fried for breakfast, boiled or roasted for dinner, and sliced cold from the roast or

* Read at the 47th Annual Meeting of the Iowa State Medical Society, held at Des Moines, Iowa, May 18, 19 and 20, 1898.

fried for supper. The amount of meat eaten by the farmers is equivalent to six ounces of beef a day for each adult. In town the merchants and professional men average eight and ten ounces a day. More meat is eaten in winter than in summer because it is the easiest food obtainable. The excessive meat eating mentioned by Dr. Purdy[6] as one of the American dietetic errors cannot, it seems, apply to Iowa farmers. The amount eaten here is below Mrs. Richard's ideal ration.[7] The cooking is, however, greatly at fault, and produces harmful results. The animals are killed too young, and are eaten too soon after butchering. The best animals are exported, and there is much waste in buying particular cuts which, though having less nourishment, poor methods of cookery demand.

Potatoes are eaten at two meals every day. For dinner they are usually boiled without the skins, thus losing the salts[8] valuable to the economy. For breakfast or supper the potatoes (boiled) are sliced and fried in lard or butter. This dish, fried potatoes, is one of the most universal foods of our people. The amount of potatoes eaten averages ten ounces a day for each adult, which is excessive when added to the other carbohydrates consumed. To the excessive use of this food can be attributed the gaseous distention of the stomach and bowels which is so common and which is relieved by the restriction of the fried potatoes.

Bread forms here, as elsewhere, the most important article of diet. It is made almost exclusively of roller-process wheaten flour, and is raised with yeast. Though generally fairly well made, through ignorance of the fundamental principles involved in the manufacture (being usually home made) the bread is frequently heavy and indigestible. No whole-wheat bread is used except in a very few families. Corn bread is occasionally seen. Rye bread is even less common. Considerable bread is eaten at every meal, and with the other carbohydrates consumed gives an excessive ration, the results of which will be referred to below. Hot bread and batter cakes, so often condemned in a diet, are not used frequently by the people here studied. In some families such cakes are eaten at every breakfast, but this is not the rule. Pies and pastry are usually eaten twice a week. Some families have pies daily, but this is rare. From the papers examined there seemed to be no relationship between the hot bread and pastry diet and the stomach trouble of these people.

Oatmeal is eaten once or twice a week. It is usually boiled in water for a short time only, and not thoroughly cooked as it should be. The advantages of long cooking at low temperature seem unknown. Beans are eaten once a week, or less frequently, usually boiled or baked with pork. Corn-meal and hominy are eaten but little. A mush is at times made of corn-meal and water, which when cold is sliced and fried in lard. This cheapest of foods, corn, in its various forms, is much neglected. Butter, in the country, though made well, is much neglected, the average amount being two ounces or less a day for an adult. Pork evidently supplies the fat needed. The majority do not use cream freely. Though many times urging the increased use of butter and cream in tuberculosis, the writer has no evidence of this in any way substituting the advantages of cod-liver oil.

Fruits, either fresh or canned, and fruit jellies, preserves, and butters are eaten abundantly by all at every meal. Tomatoes are very generally used. With these fruits, maple and sugar syrup, and molasses and honey, a large amount of the sugars is consumed. The green vegetables grown in the garden are eaten freely in the summer and sparingly in the winter. Perfect methods of preserving fruits and vegetables for winter use are much needed, but are yet unknown.

The water-supply is from surface wells. These wells are located with an eye to convenience only, and without regard to the universally present cess-pools which are an undoubted source of contamination, becoming each year a greater danger to our prairie towns. Tea is used occasionally for supper by a small percentage of the people. Chocolate and cocoa are rarely used, while coffee is drunk three times a day by a majority of the adults. This coffee is made by putting the ground brown berries in the coffee-pot, pouring on hot water, and boiling some time. The coffee-pot is often put on the stove as the first act in preparing a meal, and the decoction is boiled while all else is cooking. The coffee-pot is seldom washed, and egg is rarely used to clear the coffee. Coffee is drunk with sugar and milk or cream added. The writer has several times had attacks of dyspepsia after drinking such decoctions, and finds from the reports studied a marked relation between coffee-drinking and stomach trouble.

In cool weather the average amount of fluids taken by an adult is 32 ounces. In summer this amount is greatly increased, but on the average far too little is ingested. Alcohol, beer and wine are not generally used as part of the diet. Many men drink these beverages but not at the table nor with regularity. As to condiments, they are little used. Black pepper is consumed in moderate amounts, but chili, capsicum, tobasco, and strong sauces are used but by few of the people.

I have in a general way reviewed the food of this people, but perhaps we will be helped to a clearer

idea of their diet by a glance at some actual daily menus, three of which, typical of the representative classes, are here presented:

1. A FARMER.

BREAKFAST, 7 A.M.

Fried Salt Pork. Fried Potatoes.
Wheat Bread. Butter. Apples fried in butter and sugar.
Melted Sugar Syrup. Plum Butter.
Coffee.

DINNER, 12, NOON.

Boiled Beef. Boiled Potatoes.
Wheat Bread. Butter. Pickles. Stewed Tomatoes.
Canned Raspberries. Grape Jelly.
Berry Pie. Coffee.

SUPPER, 6 P.M.

Boiled Beef, sliced, cold. Poached Eggs.
Wheat Bread. Butter. Fried Potatoes.
Canned Cherries. Sugar Syrup. Plum Preserves.
Cake. Tea.

2. AN UNSKILLED LABORER.

BRAKFAST, 6 A.M.

Griddle Cakes. Wheat Bread. Butter.
Grape Jelly. Coffee.

DINNER, 12, NOON.

Fried Ham. Wheat Bread. Butter.
Boiled Potatoes. Baked Apples.
Pudding.

SUPPER, 6 P.M.

Wheat Bread. Butter. Oatmeal and Milk.
Apple Pie.

3. A BANKER.

BREAKFAST, 8 A.M.

Oatmeal and Prunes.
Hamburg Steak (beef) fried. Buckwheat Cakes.
Coffee.

DINNER, 12, NOON.

Roast Beef. Mashed Potatoes. Baked Squash.
Wheat Bread. Butter. Pickles.
Mince Pie.

SUPPER, 6 P.M.

Cold Roast Beef. Cranberries.
Wheat Bread. Butter. Canned Peaches.
Tea. Cake.

These actual daily menus are of typical winter-day meals. The town laborer, through a lack of knowledge in food composition and cost, has too little proteid, while the banker has too much meat in his diet. The farmer by frying his foods makes their digestion difficult, and by eating too much starch suffers from biliousness and fermentative dyspepsia.

With this picture of the peoples' diet before us, by briefly reviewing the death-causes and present prevailing diseases in the county, a relationship should be seen, if any exists, between the food and the health of the people. The mean annual death-rate in Jefferson County is 121. The mean duration of life is 41¾ years. Of the 599 deaths occurring from 1890 to 1895, 233, or 40 per cent., were due to diseases of the stomach and bowels (not malignant), diseases of the kidneys, bladder, liver and heart, apoplexy, and rheumatism, all of which may have had their origin in the improper use of food. But it is the morbidity more than the mortality that interests us. The bulk of the country doctor's practice in this part of Iowa, excepting the infectious diseases, surgery, obstetrics, gynecologic and sense-organ diseases, consists of constipation, the dyspepsias, chronic rheumatisms, and myalgias, acne, eczema, and their results. Constipation with the women is universal, and is common with the men. In summer this is somewhat lessened by the free use of vegetables and uncooked fruits. In looking for a cause for the constipation in the dietaries examined, (*a*) the small amount of fluids ingested, (*b*) the foods made indigestible by poor cookery, and (*c*) the use of foods leaving too little residue, might be considered in the order named. Dyspepsia—chronic gastric catarrh—with its results, is, in Jefferson County, one of the most prevalent diseases the doctor is called upon to treat. The dietetic errors shown by this investigation to be possible causes of this catarrh, are: (1) coffee-drinking, (2) the use of the frying-pan, and (3) the overeating of carbohydrates. Abstinence from coffee contributes toward the cure of dyspepsia, though the harm done by this beverage may be in part due to its being improperly prepared. Dr. Bedford Brown[9] says the substituting of the stew-pan for the frying-pan saved the Confederate army much sickness and many soldiers.

A common dietetic error among the people studied is the consumption of too much food, and this excess is greatest with the starches and the sugars. Fermentation, flatulent distension of the stomach and bowels, resulting palpitation of the heart and that series of symptoms denominated biliousness, are extremely common. The use of patent "liver" medicines, now so extensively sold, could be lessened by improving the general diet. It is surprising that in a study of the question-papers in no case was there any relation found between gastric troubles and the eating of pastries.

Chronic rheumatism and the myalgias are very common in Southern Iowa. These occur in the well-fed. A relationship between overeating, with too little fluid, and these diseases seems to be shown in the papers studied. Eczema and acne are undoubtedly affected by diet. These are here, as elsewhere, the most common skin diseases seen. It is probable that the dietetic errors which produce the stomach catarrh aggravate these affections.

Of course in a study of the dietetic causes of disease other things than the kinds of food eaten

must be considered. Rapid eating may cause good food to be indigestible. Bad teeth and the bacteria swallowed from a filthy mouth may help toward producing gastritis. But after considering all the elements, the following would seem to be the general dietetic causes of poor health in the communities studied: (1) Too little fluid ingested; (2) poor cookery; (3) overeating of the carbohydrates. Of these errors the first and last can be at once corrected by our prescriptions, but the overcoming of a too prevalent poor cookery is a more difficult problem. Cookery in Iowa is generally done by those who know little or nothing of the scientific principles involved. As far as is known to the writer, young women are not taught cookery or the principles of food selection in any Iowa school, with the exception of the State Agricultural College.

After some consideration, the shortest course toward the abolition of the frying-pan and the introduction of better cookery is thought to be the encouragement of the methods of Mr. Edward Atkinson.[11] It has been insisted that both meats and vegetables should be cooked at 180° C. (316.6° F.)[12]. It has been proven that economy in fuel and food flavors, ease in digestibility, and many other good purposes, are served by cooking food a long time at low temperatures. By many experiments with a wood-pulp bucket (costing 35 cents) inverted on an iron plate over an ordinary lamp, cheap food has been cooked in an attractive and digestible form. One great advantage in this cookery is that no skill is required, and young women can still devote their attention to music and Latin. The purposes of this discussion will not permit a more lengthy reference to this important subject.

The making of this inquiry has been of great interest to the writer, giving data and impressions that will be of practical use in professional work. Years of experience perhaps lead a doctor to give more attention to right-living and less to the prescribing of drugs. Many dicta relating to diet have been published and requoted until they appear as established facts. One is surprised when led to believe from his reading that excessive meat-eating causes rheumatism and myalgia, at being repeatedly told by his suffering patients that they eat but very little meat. It is a pleasure to note the valuable studies in diet made at the several Agricultural Colleges in the United States, and it was learned with regret from the President that the Iowa Station had made no such study. But it may be true that our professional statistics and the various data for our use are compiled now to too great an extent at large hospitals and in city institutions, and perhaps country doctors by some concerted study could do valuable work which would be better adapted to the use of such of us as practice in small towns.

TUMORS OF THE BREAST.[1]

BY FOUCHE WARREN SAMUEL, M.D.,
OF LOUISVILLE, KY.;
PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY AND OF OPERATIVE SURGERY IN THE LOUISVILLE MEDICAL COLLEGE; CONSULTING SURGEON TO THE LOUISVILLE CITY HOSPITAL.

CASE I.—Amanda H., colored; aged twenty-three years; married; no children; personal history good. She noticed a small hard lump in the outer and upper quadrant of the breast eighteen or twenty months before consulting me. It was not painful or tender to manipulation. She gave it no consideration for the time being, not using, as is customary with this class of people, even a local application of any kind, hence very little irritation was produced in its early history. She stated that two months after she first noticed the lump it was twice as large as when first observed. She had consulted a physician, who stated that it would have to be removed, but she absolutely refused to consent to surgical interference at that time. The growth steadily increased in size, and just before I operated upon her had begun to cause some pain and inconvenience. It had become very tender in certain areas. This I especially noticed a week or so before I removed it. I think the tenderness was due entirely to its being a very large tumor; standing out prominently it was subject to injury during the time she was at work, her occupation being that of a washwoman.

The tumor occupied the entire outer and lateral half of the mammary region; it was hard and nodulated; the breast was soft and was easily pushed to the inner and upper side of the growth. My incision was so made as to save the nipple and to hide the scar as much as possible, after the plan suggested by Gaillard Thomas. I regarded the growth as an adenofibroma which had not yet undergone cystic degeneration, and operated with a view of sparing the breast-gland if possible. Had I found it cystic, and I purposely cut into it when I had it well exposed to ascertain if a cyst were forming, I would then have removed the entire gland with the tumor. As cysts were not present, and it was completely encapsulated, the gland was left intact.

Adenomata may occur at any age but are most fre-

[1] Read before the Louisville Surgical Society.

quent between puberty and forty-five years, that is, during the period of sexual activity. They are rarely painful, the fibro-adenomata more often so than the cystic. It is reported that they frequently become painful and more sensitive to manipulation during the menstrual period. Adenomata of the mammary gland are, with few exceptions, fibro-adenomata. Since fibrous tissue is always mingled with the glandular hyperplasia, true adenomata are very rare. The excessive development of connective tissue and absence of secretion is the line of demarcation in the departure from the normal gland undergoing changes during lactation. The two varieties of adenomata are, as a rule, essentially benign; they may, however, degenerate into epithelioma. Orth makes the statement that these tumors may arise from the adventitia of the milk-duct, or the connective tissue in conjunction with the hyperplasia of gland-tissue. This fact of degenerative action in connection with recent pathologic observations have beyond doubt revealed that adenomata have a tendency to degenerate into tumors of a malignant type. This gives to the growth a peculiar clinical significance, and removal should be urged as soon as such tumors are discovered.

Mammary adenomata occur as fibro-adenomata, and cystic adenomata (so-called adenocele). As a rule, they are located in the superficial parts of the breast-gland; they may, however, be deeply situated; they are hard to the touch and glide easily about under the skin when examined. A cardinal feature of these tumors is their mobility. Fibro-adenomata, as a rule, rarely exceed the dimensions of an unhulled walnut, and are usually much smaller. The cystic variety, on the other hand, often attains a very large size, some reported weighing ten and twelve pounds. The cystic variety is also encapsulated, having a fibrous stroma with glandular acini embedded. The acini are often dilated, and intracystic growths are found springing from the walls, so-called papillomatous processes.

In the treatment of such cases the question of removal of the gland must be left to the judgment of the operator, when seen in their early stages. One general rule may be stated: When the patient is more than thirty-five years of age and the tumor very large and painful, it will be safer to remove the entire gland. Age should rank very high in estimating the extent of the operation. Mr. Clark believes that in certain cystic processes in the mammary gland an intermediate period is reached, in which, if certain stimulus is exerted, an adenoma is the result; or, if there is a predisposition and the patient is more than forty-five, a carcinoma will be the result, a most important observation, if pathologically correct, which has a special clinical significance in this class of tumors.

CASE II.—Mrs. K., a widow, aged forty-nine years, mother of several children, consulted me in February, 1895. Her history up to that time had been good. About a year, or probably less, before consulting me she observed a small lump in the upper and outer quadrant of the left breast. At the time of my first examination the tumor was about the size of a hen's egg, the skin was adherent over it, and it was apparently slightly fixed to the underlying muscle. The nipple was markedly retracted and the glands were enlarged along the outer border of the pectoral muscle and in the axilla. The tumor was very hard to the touch and the skin overlying it was of a brawny appearance and shriveled. I proposed a radical operation, after the method of Halsted. Her health at that time was not of the best, and I feared that possibly dissemination had or was occurring. I stated to her that the operation suggested was an extensive one, and not without danger. After due consideration she consented.

I removed the breast, including in the circular portion of my incision the entire gland at its base. The pectoral muscle was cut away, and the tumor was found adherent. This exposed the axilla and infraclavicular region. The axillary vein was easily seen, and all fat and glands were entirely removed as high up as the middle of the clavicle. This was as high as any enlargement of the lymphatics was found. The nerves were carefully preserved. This left a very large space at the site of the breast which could not be covered by skin, the triangular part of the flap being used to entirely close up the axilla. The extensively denuded surface was allowed to granulate, and ten days after the primary operation I skin grafted the defect with an oval piece of skin, four inches long by three and one-half inches at its widest part, from the chest on the opposite side, allowing the pedicle to remain intact, as a good blood-supply was necessary to maintain the nutrition of the graft. After three days it was attached firmly and the pedicle was cut at the margin of the wound made by the removal of the breast. A considerable piece of pedicle was left, which was replaced in its original position, and assisted materially in closing the defect left by the skin graft.

This patient was well, with no sign of recurrence, in July of this year, the last time I heard from her.

CASE III.—Mrs. F. was referred to me by her physician. About six months before I saw her she had noticed a small nodule in the breast, which she said was becoming very painful and had doubled in size within this period. There was no glandular involvement, and the nipple was not retracted. The same operation as in Case II. was performed, the axilla, which was found studded with small lymphatic enlargements, being cleaned out as high as the middle of the clavicle.

In both of these patients the use of the arm is almost as good as before the operation. Microscopic

sections of both these tumors showed them to be pure carcinoma of the acinous variety.

During the year 1889 I operated in one case of cancer of the breast, and during the same year assisted in two more. From that time until 1895 I have notes of four amputations of the breast in addition to the last two cases here recorded. Deducting the last two cases, it leaves six patients operated upon by what we call to-day an incomplete method. I have been able to follow the history of four of these patients. In two cases the axilla was not invaded because at the time of the operation no enlargement was felt in the axilla; the skin over the tumor was not appreciably involved; in both the nipple was slightly retracted; the entire breast was removed by a small elliptical incision, and the fascia over the pectoral was not disturbed. In one of the cases a few enlarged glands along the free border of the pectoralis major muscle were removed. In both patients recurrence took place; in one there was local recurrence in the scar, with lymphatic involvement below and above the clavicle when she returned for treatment. In one, regionary recurrence took place in the gland above the clavicle and in the axilla. In both instances a secondary operation was refused. In the third case a secondary operation was permitted. The recurrence was first noticed in the scar as exuberent granulation tissue, and occurred about three months after the primary operation. The secondary operation consisted of excision of the granulation tissue and the use of a cauterizing paste, composed of sulphuric acid and charcoal. Before the healing process was nearly completed enlargements in the axilla and above and below the clavicle were easily felt.

Recurrence took place in the four patients in three, six, seven, and ten months respectively. The prognosis in one upon whom a secondary operation was performed was considered at the time of the primary operation most favorable, but recurrence was more rapid than in the others, in which the tumor was larger and the skin found to be slightly adherent. In the two cases in which the axilla was invaded, enlargements were felt in both before the operation, and these enlargements were found to be very numerous and matted together when the axilla was fully exposed. In each instance the axilla was cleared, as was the practice then, of all glands that could be felt and seen, but the pectoral fascia was not removed. Local recurrence took place in seven and ten months. The glands were so enlarged in one case twelve months after the second operation as to produce edema of the arm. Excruciating suffering was experienced by this woman before she was relieved by death.

I am aware of the fact that operation after operation has been performed upon patients and their lives prolonged for many years, yet they all seem to have been incomplete operations from the first, and there are few patients who can be persuaded to submit to these multiple operations, which after all hold out only a slight chance for anything in the way of permanent relief, for there are reported cases in which even the second and third operations have been done and the patients died of internal metastases in less than twelve months after the primary operation. Observation goes to show at this time that if success is to attend operations for breast cancer, they must be done early and must be complete. I would designate as an early operation one performed before any enlarged glands are demonstrable along the border of the pectoral muscle, and before the skin has become involved in the infiltration. I regard this period early, for the rule among patients is to keep away from their physicians for at least three to six months after a nodule has been discovered, and ordinarily they do not present themselves for treatment until the tumor begins to enlarge, becomes painful, and in a majority of cases not until the skin has become involved.

The systematic cleaning out of the axilla was first advocated and practised by Volkmann, Billroth, and Küster, whose results were probably the best obtained until within a short period of the present time. Although these operators labored faithfully to master the disease by constantly extending their operative measures, local recurrence in their practice was enormous. Even as late as 1893, Bland Sutton laid great stress upon the importance of avoiding opening the axilla, if possible, on account of the added risk to the patient. Volkmann, Billroth, and others were systematically cleaning out the axilla and removing the pectoral fascia in the early stages of breast cancer long before this, and Volkmann removed part of the pectoral muscle when satisfied of its involvement. To the last-named operator we owe the statement of the difference, prognostically, between the involvement of the pectoral muscles by extension of the growth and the invasion of the muscles by metastasis. This may be explained, as Ludwig says, by the cellular elements entering the lymphatic system of the muscle and being carried rapidly by the muscle contraction throughout its fibers. It is not necessary that the tumor be adherent to the muscle in order that the muscle itself be involved, and, as stated by him, carcinoma may be embedded in muscle and still not *involve* the muscle, by virtue of the fact that the lymphatics spread out upon the fascia and do not follow the blood-vessels into the connective-tissue septa between

the muscle-fibers, in which theory he is supported by Heidenhain, whose investigations have proven that the direction of the lymphatic current is from muscles to fascia and not in the reverse direction. So much was Volkmann impressed with the fact that the fascia is involved long before the muscle, that he adopted a method of operating which has become classical. It has been his advice to remove the fascia of the pectoral as clean as possible, and he asserts that when carcinoma has made its way into the lymphatic vessels it has invaded the fascia down to the surface of the muscle, however thick the layer of fat between the breast-gland and muscle has been, even if it still remain perfectly movable.

As to the ultimate results, or what might be called radical cures after complete operation, most surgeons accept even yet the views of Volkmann, that at least three years must pass before a radical cure can be claimed. His method of cleaning the fascia from the pectoral muscle, a wide incision, with systematic clearing out of the axilla, have given the best results up to the present time, but it is by the method of Halsted, in this country, that the radical cure of breast cancer gives far better results if the patient is operated upon before dissemination has taken place.

The following table is from Halsted's paper, published in 1894:

Operator.	Time.	Number of cases.	Local recurrence. (Per cent.)
Bergmann	1882–87	114	51–60
Billroth	1867–76	170	82
Czerny	1877–86	102	62
Fischer	1871–78	147	75
Gussenbauer	1878–86	151	64
Kõnig	1875–85	152	58–62
Küster	1871–85	228	59.6
Lücke	1881–90	110	66
Volkmann	1874–78	131	60
Halsted	1889–94	50	6

Halsted says: "The prognosis at the time of the operation was recorded as hopeless or unfavorable in 27 of the 50 cases of complete operation. In every one of the 50 cases some or all of the axillary glands were cancerous."

In the two cases reported I followed the method of Halsted in every particular. In the case of the first patient nearly three years have elapsed, and in the second, a year and five months since the primary operation. In neither has local or regionary recurrence been discovered. The patients remain in good health, with almost perfect use of the arm. I am convinced that the operation is incomplete unless the pectoral fascia and muscles are removed. It is never known until after a microscopic study of the muscle-fibers has been made whether or not they are involved, and as they are involved before decided lymphatic involvement is palpable, it is poor surgery to leave the muscle behind, the loss of which does not entail a great amount of disability as far as the arm is concerned.

THE OBSTETRIC FORCEPS AS A CAUSE OF MENTAL AND NERVOUS DISEASE; A PROTEST.

By V. M. REICHARD, M.D.,
of Fairplay, Md.

It has apparently become almost an accepted dictum among certain alienists and neurologists that, given a child in whom there is an existing mental or nervous defect and a history of forceps delivery, the relation of cause and effect of necessity exists. Indeed, judging from the statements one sees in medical literature, forceps delivery necessarily entails great risk to the future usefulness of the child. Against this trend of opinion I want to record a very positive protest born of a fairly large experience in general practice, having been able to follow the history of my cases through years.

Cerebral membranes and tissues are in far more danger, it seems to me, from prolonged and unassisted labor than from any pressure which may be applied to the head by the proper use of the forceps. If there be maladroitness of application, that is a fault not chargeable to the instrument but to the operator. Avoidable damage to the fetal or maternal structures must be charged to the proper account. No surgeon would tolerate condemnation of his pet operation because some one else with less skill, or who failed to comprehend its principles, had unfortunate results. I hold that vastly more damage is done to the structures involved in mental and nervous processes by injudicious and incapable delay than by the timely and proper use of the forceps. The following case will serve as an illustration:

On October 5, 1889, I was called in consultation to see Mrs. L., with a view to performing craniotomy. I found her to be a large, fat woman, in labor with her sixth child. All her previous labors had been prolonged and difficult. When I saw her she had been in labor twenty-four hours, with hard pains nearly all the time. The attendant had attempted to deliver with forceps, but considered the head too large to pass through the parturient canal. A vaginal examination revealed a large boggy mass projecting downward. Neither fontanelle nor suture-line could be made out. The os was dilated to its extreme limit, and high examination showed the head to be lodged on the brim of the pelvis. The long forceps was applied, but the grip was insecure and little force could be applied in traction before it slipped. By external manipulation and very steady, gradual, and

patient traction the head at last passed the obstruction and the woman was speedily delivered of a living male child weighing eight and a half pounds. Its appearance was monstrous; it looked double-headed, with one head superimposed upon the other. It was unconscious when born and remained so for a week. Soon after birth it was taken with tonic convulsions, and during the first week had more than one hundred such spasms. It gradually recovered and began to thrive and grow. He is now a strong, sturdy boy at school, wearing a 7⅜-hat. While fairly intelligent, he is a moral terror, and among all the children he is the only one with a neurotic tendency. Any slight indiscretion in diet brings on the most dreadful tonic convulsion, from which he does not recover for hours. I have always felt that had this child been delivered twelve or eighteen hours sooner his peril would have been avoided.

I have seen children injured in delivery with forceps, but the injury was due to the malformation of maternal structures and not to the forceps. It has become a question with me as to what extent external force short of actual rupture of the meninges will develop cerebral troubles in the child. Any one who has seen many occipitoposterior deliveries will be struck with the facility with which cerebral tissues change their relative position, with no resulting harm. A long wire-drawn head, bearing no resemblance in shape to the normal fetal head will gradually right itself with not a particle of harm done. According to this ultra school of neurologists every occipitoposterior delivery should result in a crippled brain. In thirty of these patients, some of whom are now more than twelve years of age, I have yet to see the first bad result. Indeed, if there be any physiologic reason why the bones of the fetal head should be so freely movable it is that they, and *pari passu*, the cranial contents, may allow such change in relative position as the exigencies of delivery demand.

To those who have done even a small amount of obstetric work it must have been a matter of frequent notice how readily the bones of the skull bend when pressure is applied, as in rectifying faulty head positions, and yet the child be absolutely devoid of symptoms pointing to brain injury. True, these depressions and bendings of the cranial vault are but momentary and disappear as soon as the force is removed. The following case, however, shows how entirely void of ill effect even a permanent depression may be:

On July 17, 1896, Mrs. D. fell into labor with her first child. Though slow, her labor advanced satisfactorily until the head was on the perineum, when the woman's vital powers began to flag. Applying the short forceps the fetus was easily delivered when, to my horror, I found a depression almost as large as a silver dollar over the right frontal region made by the point of the forceps-blade. I, of course, expected all sorts of dreadful results and watched the child with great interest. His development has been perfectly typical. The depression was gradually obliterated as the bone solified and now, more than two years after, there remains no trace of it and the child is above rather than below the average in mental and physical development.

I, of course, like every other man in general practice, have seen children with mental and nervous defects, but in the cases coming under my care there has been absolutely no history of forceps delivery. All those of defective mentality have been born normally, the labor in every case being exceptionally easy.

That the forceps, badly applied, is capable of doing damage I am not denying; that the pulling of a large head through a small and contracted pelvis may do damage to the head, I also am not denying. This last needs must be, and in deciding what shall be done it is a question of risk to life or usefulness of the child, or submitting the mother to a capital operation. These cases must each be decided individually and in each the individual risk must be taken, but that the ordinary use of the forceps, in any case in which it alone is indicated, and is used simply to supplement the waning or exhausted *vis a tergo*, is in itself a source of danger to the child's brain I have failed to observe, and against the theory that it does so I must most emphatically protest.

WAR ARTICLES.

LEITER GENERAL HOSPITAL—SOLDIERS' AID COMMITTEE—HOSPITAL TRAIN—DISCHARGES FOR DISABILITY.

CHICKAMAUGA PARK, GA., August 7, 1898.

THE writer made his first visit to Leiter General Hospital last week, and was given a cordial welcome by Major C. E. Carter, United States Volunteers, who is in charge. The Major and myself had not met for nearly fifteen years, having separated at old Fort Thomas, Arizona, during a campaign against the wily Apaches. Leiter Hospital is running at its full capacity, the vast majority of cases, perhaps ninety per cent., being of typhoid fever. The Brand method of treatment is carried out, and gives a mortality of from 1 in 16 to 1 in 18 cases, or from 6.25 per cent. to 5.11 per cent. As high as 1000 pounds of ice have been used in one day to furnish the required degree of temperature to the baths. It is customary to grant furloughs to patients convalescent from typhoid fever in this hospital. Surgical cases have not been so abundant as in the earlier weeks of the campaign. Operative cases occur not infrequently, however, necessitating a resort to the knife for appendicitis, or to the splint for fracture of the long bones. Many alterations and improvements, both within the building and on

the grounds, are in progress, and the institution under the excellent management of Major Carter is bound to flourish and fulfil its useful mission.

I was recently in receipt of a letter from the Soldiers' Aid Society, through its secretary, Mrs. Daniel N. Bash of Peoria, Ill., offering assistance in the way of supplies—jellies, blackberry cordial, pajamas, and other needful articles—for the sick of this Division Hospital and Ambulance Company, and we responded with gratitude to the call. There are now about 300 sick in our Division Hospital, and the Ambulance Company is kept on the *qui vive* to supply the ambulance service. This morning at 5.30 o'clock sharp eighteen ambulances were in waiting at the Division Hospital for the transportation of typhoid-fever patients to Lytle, whence they will be transported by hospital train to Fort McPherson, Ga., after swelling the list to 134 by additional cases from the First Division Hospital of this corps and other sources. The sick were carefully but expeditiously unloaded from the ambulances, and ninety-two of those unable to sit up were placed in lower berths of tourists' cars, one to each berth, on a comfortable mattress on white linen sheets. The upper berths are used when the necessity exists, and they serve to accommodate the convalescent patients. Major Charles Richards and Captain Henry R. Stiles, Medical Department, United States Army, were charged with the care and transportation of the sick by hospital train, and after unloading these at Atlanta, will probably go on to Tampa, Fla., for sick or wounded awaiting them there.

Certificates of discharge for disability for diseases not incident to the service, or rather for diseases or disability existing prior to enlistment, still continue to be handed in to boards of three medical officers convened for the purpose of scrutinizing the certificates and approving or disapproving them before forwarding to authorities competent to order discharge from service. Those certificates submitted, for example, for asthenia consequent upon typhoid fever, are usually disapproved and a furlough recommended. In this way a good man may be spared the service, and the Pension Department not unnecessarily burdened with claims for temporary disability. Far too frequently cases are brought before the board with the history of maiming, or physical deformity, or mental incapacity, years of epileptic seizures, moral obliquity, luetic manifestations, and other disabling conditions existing prior to enlistment. Not too frequently that the Army should find an early riddance of them, but too frequently that those so disabled physically, mentally, or morally should have in some instances withheld pertinent facts of their past or present physical ailments from the knowledge of the recruiting and medical officers, or have evaded their scrutiny on account of careless or faulty methods or duty perfunctorily or negligently performed. The stringency of our recruiting regulations is still in effect, and it does not seem to be the purpose of the Administration to let down the bars during war times, and more and more each succeeding year am I impressed with the paramount importance and weighty moral responsibility pertaining to the functions of the recruiting officer and medical examiner of recruits.

It is a matter for contemplation and for serious reflection by the medical staff of the Army that within every three years the whole enlisted force is brought before it for judgment to be pronounced as to their physical and mental fitness and capacity for performing effectively the duties of the soldier. Recruiting and medical officers should keep constantly before their mind's eye Tripler's inimitable description of the leading characteristics of a good constitution: "A tolerably just proportion between the different parts of the trunk and members; a well-shaped head, thick hair, a countenance expressive of health, with a lively eye; skin not too white, lips red, teeth white and in good condition; voice strong, skin firm, chest well formed, belly lank, parts of generation well developed, limbs muscular, feet arched and of a moderate length; hands large. The gait should be sprightly and springy, speech prompt and clear, and manner cheerful. All lank, slight, puny men, with contracted figures, whose development is, as it were, arrested, should be set aside. The reverse of the characteristics will indicate infirm health or a weakly habit of body; loose, flabby, white skin; long cylindrical neck; long, flat feet; very fair complexion; fine hair; wan, sallow countenance," etc., if they would have a regiment or an army of approximately physically perfect recruits not encumbering the sick recruits with other diseases than the infectious fevers which depend so largely on conditions or environments for which the recruit is not individually responsible, nor deranging the effectiveness of an organization for the time being by frequent resort to certificates of discharge for disability for diseases incurred prior to enlistment. The boards are rapidly weeding out the incapable and incapacitated men, and recommending furloughs in many cases to convalescents who give promise of early usefulness.

HENRY I. RAYMOND, M.D.,
Major and Surgeon, United States Volunteers.

SICK AND WOUNDED SOLDIERS FROM THE BATTLE-FIELDS OF SANTIAGO, CUBA, AND VICINITY AT THE UNITED STATES MARINE HOSPITAL, STAPLETON, STATEN ISLAND.

BY GEORGE W. STONER, M.D.,
SURGEON IN COMMAND, UNITED STATES MARINE HOSPITAL SERVICE, PORT OF NEW YORK.

OF the 100 sick and wounded soldiers admitted to this hospital July 16, 1898, a large majority received their wounds on the first day of July, some on the second and third days of the month, and a few as early as June 24th. The wounds in most cases were more than two weeks old, and in some cases more than three weeks old, when the patients were admitted, hence the brief and necessarily incomplete description of some of the cases here reported.

Some of the wounds were slightly infected on arrival, but the majority were in good condition, proving the value of the first dressing properly applied and with due regard to asepsis. Forty per cent. of the men were

wounded in the upper extremities, 29 per cent. in the lower extremities, 10 per cent. in the head and neck, 5 in the chest, 2 in the back, and 1 in the abdomen. Four suffered from the effects of heat (sunstroke), and one from concussion of the brain and spinal cord. Many cases were complicated by malaria and diarrhea, and there were two cases of enteric fever (typhoid). Seventeen additional patients, all medical, and chiefly malarial cases, were admitted July 30th, having arrived at quarantine the day before on the transport "Leona."

Many of the surgical patients required comparatively little treatment beyond the necessary changes of dressings, and those wounded in the upper extremities and a number of others have been able to be up and about the hospital and grounds since the day of arrival. Nearly all the wounds were produced by the Mauser bullet, two by shrapnel, and two by pieces of shell, and in one case by shell explosion. The wounds are nearly all perforating. In a few cases the ball remained lodged in the body. Removal was easily effected in two cases by the aid of the X-ray, but no attempt has been made to remove balls lodged in the chest, of which there are two cases, both the men doing well. The wounds produced by the Mauser bullet in many cases were not unlike a large needle wound, the wound of entrance and that of exit in most instances seeming to have been about the same as to size and freedom from laceration. In a few cases the wound of entrance was the larger, and in a few others the conditions were exactly the reverse.

There are six fractures of the upper extremities, three of which are comminuted. The treatment of the infected wounds, and in fact of all the wounds, has consisted for the most part in antiseptic irrigation, followed by iodoform-gauze dressing. In some cases peroxid of hydrogen was first used to cleanse the wound. These measures, together with good nursing, good food, pleasant surroundings, and plenty of air space have thus far given as good results as could reasonably have been expected.

In submitting these notes, I beg to express my obligations to Assistant-Surgeons H. S. Cumming and H. B. Parker, and Acting Assistant-Surgeons R. C. Craig and T. B. McClintic, and Interne Albert Butler for valuable assistance in preparing the same.

CASE I.—Joseph Bily, aged thirty-one years; native of Austria; member of Co. G., 16th Regiment. Wounded, July 2, 1898. Wound of entrance in frontal bone over left eye; exit, middle of posterior border of sternomastoid muscle, evidently passing through brain tissue. July 16th, complained of slight pain and total loss of vision in left eye, but the natural appearance of eye is unchanged, save slight injection of conjunctiva. 18th, wounds healed. 21st, slight paroxysmal pain; 22d, slight pupilary reaction, but total blindness of left eye. 25th, comfortable. 31st, doing well.

CASE II.—Frederick Zeitz, aged thirty years; band musician, 16th United States Infantry. Wounded, July 1, 1898. Was lying down when struck by Mauser ball. Wound of entrance in middle of and just anterior to center of ramus of inferior maxilla of the left side, the ball entering sideways, having first hit the earth in front of him. The ball entered the antrum, destroying a considerable portion of the anterior surface and alveolar border of the superior maxilla; going downward and backward, it emerged through the palatal and nasal portion of the same bone, opening into both inferior meati and mouth. Its course was then checked by the molar teeth of right side. He removed the bullet with his fingers, it lying free in the oral cavity, and then applied a first-aid bandage to try and control the profuse hemorrhage. Surface dressings were applied daily for the next six days, when hemorrhage completely ceased; was afterward removed to the transport "Olivette" and sent North. On admission the antrum and both nasal cavities were found filled with pus, mucus, and fragments of bone. These were removed, and cavities frequently irrigated with mild antiseptic solution; granulation formed rapidly, and may completely close wound in mouth. The external wound has now (August 2) completely healed. Speech and swallowing are interfered with to a considerable extent.

CASE III.—Paul A. Barteline, aged nineteen years; native of Germany. Co. D., 16th Infantry. Wounded, July 1, 1898, by bullet entering on right side of face, passing through ramus of jaw to opposite side, downward and backward to point of exit below and behind left ear, near the insertion of sternomastoid muscle. July 16th, wound in good condition, apparently healed; no pain, but mouth cannot be opened more than about 2 centimeters. July 31st, improving.

CASE IV.—William Clark, aged twenty-seven years; native of District of Columbia. Co. E., 24th Infantry. Wounded by a bullet from a sharpshooter in a tree-top. Wound of entrance frontal bone above right eye; first point of exit inner side body of inferior maxillary bone, reentering muscles of shoulder, and emerging at inferior angle of scapula. July 16th, small wounds of entrance and exit nearly healed, except wound of back, and this is granulating. Total blindness of right eye from probable detachment of retina. Cornea opaque; muscular movement of eyeball not affected. 18th, some pain in right eye. 31st, improving, except as to eyesight. August 2, doing well.

CASE V.—David Holden, aged thirty-three years; native of Tennessee. Corporal, Co. F., 24th Infantry. Wounded, July 1, 1898. Bullet entered skull behind right ear and emerged on left side of nose just below inner canthus of left eye; some hemorrhage. July 16th, complained of headache and some defect of hearing in right ear. 19th, small quantity of purulent matter removed from right ear. 20th, headache and soreness of right side of face. Irrigation of warm solution of borax ordered for ear. 25th, ear improving. 28th, pain right side inferior maxillary. 30th, pain at angle of jaw. 31st, improving. August 3rd, wounds are healed. Lateral motion of jaw limited by reason of injury to pterygoids. Some sensory paralysis in region supplied by orbital branch of fifth nerve. Membrana tympanum was ruptured, and there was marked tinnitus, but that has nearly all gone.

CASE VI.—Charles H. Hoadley, aged nineteen years; native of Massachusetts. Co. K., 2d Regiment, Massachusetts Volunteers. Was wounded July 1, 1898. Bul-

let entered right side of neck, and apparently passed upward to ramus of jaw. No wound of exit. On admission to the United States Marine Hospital, July 26th, wound was healed, and patient was in fairly good condition, save some headache and restlessness at night. July 21st, headache all gone. Feels first-rate. July 28th, X-ray shows bullet, or portion of a bullet, above hyoid bone, behind trachea, near common carotid artery, where for the present at least it is apparently doing no harm, and patient declines further treatment. Furloughed July 30, 1898.

Case VII.—James Davis, thirty-two years old; nativity, North Carolina. Co. F., 24th Infantry. While on the firing-line on July 1st he was struck on the forehead by a missile of unknown character and remained unconscious for an hour or so, losing "a lot" of blood. When admitted July 16th his wound was nearly healed and no complications had occurred. The missile raised a horse-shoe-shaped flap 7 cm. in length, its convexity downward, and 5 cm. above the glabella. The wound is now healed. There has been no indication of any wound to the frontal bone.

Case VIII. — James A. Bingham, aged thirty-eight years; nativity, Indiana. Corporal, Co. G., 2d Infantry. Wounded, July 2, 1898. Bullet entered one inch below right shoulder-joint anterolaterally, passing directly backward through muscles, but emerging three inches from point of entrance. July 16th, wound in good condition. Says he had some fever on the voyage from Santiago to New York. 17th, some pain on motion. Has troublesome cough and bronchitis; no fever. 21st, feeling better; cough less annoying. 24th, says his "bones ache;" bowels loose. 27th, has temperature of 38.2° C. (100.6° F.); pulse, 80. 29th, temperature 37.2° C. 30th, temperature up to 38.4° C. (101.2° F.). August 2d. Temperature has risen one degree every afternoon the last four days, dropping back half a degree in the morning, and is now—evening—up to 40.2° C. (104.4° F.); pulse, 100; bowels quite loose; no pain. Typhoid fever of severe type.

Case IX.—Willis E. Parker, aged twenty-four years; nativity, Illinois. Sergeant, 10th United States Infantry. Wounded, July 1, 1898, in upper third left forearm, middle of left arm, left shoulder, neck, and right shoulder; a wound of entrance and exit in each locality; ten wounds in all. First wound of forearm with comminuted fracture of radius, wound of entrance being on exterior surface of arm over ulna about four inches below elbow-joint; ball went downward and inward, fracturing the radius with slight comminution, and made exit over inner border of radius about two inches lower on arm than wound of entrance. The arm being strongly flexed at the time, the ball passed through skin and fascia over biceps, and again over deltoid; reentrance at insertion of, and passed through right, sternomastoid muscle and out at center of right clavicle; reentered at outer extremity of and below clavicle, and lodged under skin over trapezius muscle, about center of superior border of right scapula, where it was removed by skin incision. Hemorrhage free at all wounds; first-aid dressings applied one hour after wounds were received, and again next day. Left forearm was dressed with a wire splint on July 2d, and on July 8th was encased in plaster dressing on the transport "Olivette." On admission arm was examined and fracture located; some callous but no union; splint applied. August 3rd, fracture firm; all wounds healed; utility of parts good.

Case X.—Andrew Kretschener, aged thirty-three years; native of Germany. Corporal, Co. C., 16th Infantry. Wounded, July 1, 1898. Bullet entered arm at middle of deltoid muscle externally, and passed directly inward, producing a comminuted fracture of humerus, and, entering the chest between fourth and fifth rib, passed downward and backward through the lung to final point of exit over spinous process of twelfth dorsal vertebra. July 16th, has antiseptic dressing and wire splint on arm. Hemoptysis was marked for some days, but ceased on the 14th; has some pain in arm. 18th, antiseptic dressing renewed, and arm and forearm placed in wire splint. 23rd, wounds of soft parts of arm healed; chest wounds healing; angular splint applied to arm. 31st, doing well.

Case XI.—James Grimes, aged thirty-five years; native of Kentucky. Corporal, Co. B., 24th United States Infantry. Wounded, July 1, 1898, in left forearm. Perforating gunshot wound, the ball entering on inner border of radius, and made exit on outer border of ulna, transversely across forearm, and about four inches below the elbow-joint. Both entrance and exit were enlarged and infected; there was a fracture of both bones of forearm, the radius being comminuted. Hemorrhage was slight; first-aid dressing immediately applied. July 2d, dressing was removed; anesthetic given and loose fragments of bone removed; wire splint applied. On admission dressings contained some pus, but wounds were in fair condition, cavity of radius filling up with granulation, bony union at fracture of ulna. Had seven malarial paroxysms on July 17th. August 3rd, forearm still in splints and doing well.

Case XII.—Edward J. Albertson, aged twenty-three years; native of New Mexico. 1st. Volunteer Cavalry. Wounded, July 1, 1898. Penetrating wound by Mauser ball; wound situated just below and internal to styloid process of radius on posterior surface of arm; is almost healed; a superficial dressing applied; maintains the ball is still in wound; some stiffness of thumb and constant pain. Wound examined on July 26th and found entirely healed; there was an area of fluctuation below wound, and, on making incision a considerable quantity of pus was evacuated. Ball could not be located. July 27th, was examined by X-ray. A Mauser ball is seen lying along side of and parallel with metacarpal bone of thumb. The incision made yesterday was slightly enlarged under cocain and the ball extracted. Is now rapidly healing.

Case XIII.—Charles F. McCoy, aged thirty-eight years; native of Pennsylvania. Private, Light Battery F., 2nd Artillery. Wounded July 2, 1898, in elbow-joint, right arm. Wound of entrance about one inch above external condyle; wound of exit about two inches below same point. The arm was flexed at the moment of

injury; the ball passed through the elbow-joint, apparently doing very little damage. Both wounds are small, and healed rapidly. Forearm has a range of motion of about 25° without producing pain. Has almost complete loss of power in muscles of forearm; slight motion in thumb; fingers powerless. Massage will be begun in another week; it usually gives excellent results.

Case XIV.—Herman Nicolaz, aged thirty-seven years; native of Germany. Private, Co. F., 6th United States Infantry. Wounded in forearm, July 1, 1898. Wound of entrance two and one-half inches above styloid process of ulna on extensor surface; wound of exit one inch above same point on flexor surface. Produced a compound comminuted fracture of ulna; fragments were removed and drainage used. Wound is in good condition and healing rapidly. The motions of the wrist-joint and fingers will not be interfered with. Had also tertian type of malaria; responded quickly to quinin.

Case XV.—John F. Mack, aged twenty-nine years; native of Ireland. Private, Co. E., 7th United States Infantry. Wounded, July 1, 1898, by Mauser ball. Entered first at center of axillary border of scapula; after going just beneath the skin for three inches it emerged and entered the arm at junction of post-axillary fold, going through triceps, humerus and deltoid, emerging just above the deltoid tubercle. The first dressing was applied by comrades, considerable pressure being used to control hemorrhage. The next dressing was applied about an hour after the reception of the wound; it consisted of a surface-dressing to all wounds except wound of exit; here a plain gauze drain was inserted. This dressing was renewed on July 5th; on July 14th was examined, and wound of exit found infected, the infection extending into medulla of bone; was redressed, a plaster cast being applied. On the 17th, on admission, the hand and forearm were markedly edematous and dressings saturated with pus; they were removed and wound thoroughly cleansed, a drainage-tube inserted, and the arm loosely dressed in wire splint. Two days later this dressing was removed and the arm found to be in fairly good condition; edema had disappeared; same dressing applied every second day since admission. Bone was found to be perforated and transversely fractured. It is interesting to note that the three wounds that had superficial dressings applied to them healed rapidly, while the one that was the subject of interference became infected and changed the whole course of the injury.

Case XVI.—Benjamin J. Hardman, aged twenty-two years; nativity, Alabama. Co. E., 24th Infantry. Wound was probably caused by a large caliber bullet from a sharpshooter in the trees striking the limb while the forearm was fully pronated. Patient received the wound July 1st, and it was dressed July 2d by surgeons at Siboney. The missile entered 7 or 8 cm. above the wrist-joint about one-third way between the outer and inner sides of the right forearm, passing thence downward, inward, and backward (as the arm was pronated), to an exit about 2 cm. above the styloid process of the radius just external to the radial artery. When first seen here, July 16th, the dressings were full of pus. The entrance wound was 3 cm. in diameter and surrounded by unhealthy granulations; the radius seemed to have been blown away (or removed) in part along the course of the missile so as to leave the intact articular portion connected with the shaft by a slender anterior connection. The exit was fully 5 cm. in diameter, covered with unhealthy granulations. A linear eschar running upward 25 cm. shows an incision made to remove splinters of bone. Through-and-through tube-drainage, with iodoform and bichlorid-of-mercury dressing, have been used, pieces of bone removed from time to time, and the wound is now healthy and healing.

Case XVII. — Michael McCartin, aged twenty-six years; nativity, Ireland. Sergeant, Co. G., 9th Massachusetts Volunteer Infantry. Wounded in finger of right hand, July 2, 1898. Ball first struck dorsal surface, second phalanx, second finger, producing contused wound, then struck second phalanx, index-finger, same hand, producing a compound comminuted fracture, splintering the bone throughout its extent. Was dressed at once and frequently afterward. Wound become infected, sloughs forming. On July 19th had secondary hemorrhage from index-finger. July 20th, finger was amputated at first joint. On August 1st had malarial paroxysm. Quinin treatment successful. August 4th, almost completely healed.

Case XVIII.—Isom Taylor, aged twenty-seven years. Troop F., 10th Cavalry. During a charge, July 1, 1898, a Mauser bullet entered the exterior aspect of the left forearm 12 cm. below the elbow-crease and, passing upward, backward, and outward, made its exit through the joint just on a level with the superior aspect of the olecranon as the arm was semiflexed. The wound was dressed at the Siboney hospital, and again on the "Olivette." July 16th, he was admitted here, and when dressed a rubber drainage-tube was found which passed 3 cm. into the elbow-joint through the exit wound. A linear eschar 5 cm. long showed incision made by surgeons. Exit wound was 1 cm. in diameter. Pus escaped from tube. Wound of entrance was healthy and was open for 5 cm. X-ray examination shows a separation of the head of the radius from its articulation, and a transverse fracture of the neck of the olecranon. Forearm was half pronated, and only a few degrees toward supination is possible. Wound is progressing very nicely, the local swelling and temperature has disappeared, and the drainage-tube shows little secretion.

Case XIX.—Shelby F. Ishler, aged twenty-one years; nativity, Illinois. Troop D., 1st Volunteer Cavalry. Wounded, July 1, 1898, in two places: first by Mauser ball in right thigh, ball entering at inner side about middle of shaft of femur and going transversely outward through skin, fascia, and quadriceps. Wound of entrance and exit extremely small and nearly healed on admission. The second and severest wound is in the right forearm, involving the wrist-joint. Wound of entrance near wrist-joint on anterior surface of forearm and between the radius and ulna; this wound is about one inch in diameter. The ball passed backward and upward, producing a compound comminuted fracture of the

radius. The wound of exit on the posterior surface is about two inches in diameter, the structures being contused and disorganized. It will be noted that this wound was produced by a large caliber ball (.45 to .50 cal.), of slow velocity and considerable momentum. It approaches in severity the combined wounds of bone and soft parts produced by the Minie-ball used during the Civil War; fortunately, these wounds are rare. It will be noted also, that twenty-five years ago the severity of this injury would have justified amputation, while to-day, August 2nd, it is almost healed, the deformity is not great and the hand will at least have partial restoration of function.

CASE XX.—Joseph B. Miskewicz, aged twenty-seven years; native of Poland. Co. F., 3rd U. S. Infantry. Wounded, July 1, 1898. Wound of entrance on flexor surface of forearm, about four inches above wrist-joint; wound of exit on radial side of extensor surface of forearm, about one inch nearer wrist-joint. Wound produced by round or large caliber conical ball; wound of entrance about one inch in diameter; wound of exit about same size. Produced compound comminuted fracture of radius. First-aid dressing applied in one-half hour. The next day, July 2nd, anesthetic was given, wound of exit enlarged, an incision about five inches in length along radius, fragments of bone were removed, and several inches of radius resected. Wound stitched. Became infected around wound of exit and entrance, and suppurated until admission. Wound cleaned and dressed. Next day wound was considerably inflamed and hand edematous from use of iodoform; sterile dressing applied, and since then healing has been rapid.

CASE XXI.—William B. Kronskop, aged twenty-five years; nativity, Ohio. Co. F., 17th U. S. Infantry. Wounded, July 2, 1898, by Mauser ball; hemorrhage was slight; first-aid dressing applied almost immediately afterward; has been dressed at regular intervals since. Wound of entrance two and one-half inches below acromial extremity of clavicle on anterior surface of arm; wound of exit midway between, and four inches above, condyles of humerus posteriorly. Both wounds are the same size, being about one-quarter of an inch in diameter, and healed uninterruptedly. Course of ball was through skin and fascia, deltoid and triceps muscles.

CASE XXII.—William Apitz, aged twenty-five years; nativity, Kansas. Co. C., 6th Infantry. Wounded, July 1, 1898. Missile seems to have entered palm of hand, causing severe laceration and necessitating amputation of index and middle finger, which was done by the surgeon of the regiment. July 16th, some pain; wound infected; dressing changed; wound cleansed and packed with iodoform gauze. July 20th, considerable pain. July 21st, wound cleansed with peroxid of hydrogen; dressed with iodoform gauze, and hand laid on a splint; dressing changed at intervals of two days. July 31st, improving.

CASE XXIII.—Justa Mustelier, aged forty-two years. Sergeant, Cuban Volunteers. Right forearm was shattered and severed in its lower portion by an American shell, July 23, 1898, and a modified skin-flap amputation done in its upper-third, June 25th, by the surgeon of the United States steamship "Olivette." When admitted, July 16, there was slight local temperature and some pain, both of which disappeared after wet antiseptic dressing. July 19th, patient had pains in abdomen, headache, and a temperature of 40° C. (104° F.). Plasmodium found in his blood, and cathartic and quinin given. Temperature has since been about normal. July 26th, fluctuation and pain in joint. By small incision evacuated 25 centimeters of pus, and removed a silk ligature, since which time the wound has been healing nicely.

CASE XXIV.—John Hendricks, aged twenty-three years; nativity, Indiana. Co. D., 16th United States Infantry. Wounded by Mauser ball on July 1, 1898. The wound of entrance is small, situated a half-inch below Pouparts ligament, and just external to the femoral artery. Wound of exit posteriorly, on a plane horizontal with entrance just above gluteal crease, and about center of buttock. It is somewhat smaller than the wound of entrance, but did not heal so rapidly. The course of the ball was through the hip-joint; a single perforating fracture must have been produced, as there were no symptoms referable to bone lesion after tenderness of the wound had disappeared. On July 2nd an area of hyperesthesia developed over the area innervated by the middle and internal cutaneous branches of the anterior crural nerve. This was so intense that the weight of a sheet caused burning pain; could bear no weight on this leg on admission. On July 21st, gentle massage, and continued, with daily improvement until now, all hyperesthesia has disappeared and the patient walks with comparative ease.

CASE XXV. — Michael O'Mealy, aged thirty-eight years; nativity, Ireland. Private, Co. A., 21st Infantry. Wounded, July 2, 1898, in left buttock; ball apparently still in body; no point of exit; sitting up; slight pain. July 20, 1898, no pain, but some spasm of muscles of leg. 21st, marked spasms of muscles of thigh, painful contractions requiring hypodermic of morphin. 22nd, some fever; feels weak; said he felt as if something had given way or broken about his hip. Evening, spasmodic pain more marked; profuse perspiration. 23rd, restless during the night; temperature this A.M. 29.7° C. (103.4 F.). Pain most marked along course of sciatic nerve, and internal pudic at greater sciatic notch; no tenderness of spine. 24th, spasmodic and painful contraction of leg muscles during the night, requiring large doses of anodyne; growing weaker; temperature, 38° C. (100.4° F.); pulse, 120, Wound apparently in good condition. Probe enters to a depth of 1¼ inches only, and directed downward and inward toward tuberosity of ischium. Evening, somewhat better, but the spasms are still marked. Later, temperature, 40.4° C.; pulse, 134, and spasms more severe. 9.15 P.M., incision made down to sciatic nerve, between tuberosity of ischium and great trochanter, where pressure seemed to be, but bullet was not found; recovered from anesthetic fairly well, but spasms soon returned as severe as they were before. 25th, 4.30 P.M., unconscious; temperature, 41° C.; thready pulse. Died at 5.40 A.M. Post-mortem examination ten hours after death. Large blister noticed at

left heel, above os calcis. A considerable quantity of brownish fluid passing from nose and mouth. Upon incision along the course of the wound, the ball, shrapnel, was found about 2½ inches below the skin, in the gluteus maximus muscle, a considerable distance removed from the nerve trunks. There was some discoloration of the muscular tissue in which the ball was embedded, and slight moisture of the part, but no suppuration. A piece of blue cloth, evidently from the uniform trousers, carried in by the bullet was removed from the wound. The ball was flattened to some extent on one side. Further examination showed marked congestion of the psoas muscle, and after removing the intestines from the abdominal cavity the congestion was found to extend the whole length of the muscle, and the muscle was completely ruptured diagonally across its fibers, at a point beginning at the second lumbar vertebra.

CASE XXVI. — Peter O'Connor, aged twenty-five years; nativity, Ireland. Co. D., 8th Infantry. Wounded, July 1, 1898. Bullet entered right foot 3 cm. below inner malleolus, passing downward and forward and out at middle line of sole, between metatarsal bones. Wound healed when admitted, July 16, 1898, but patient complained of chills or chilliness, and said he had been sick for a number of days. Temperature, 39° C. (103.3° F.); pulse, 104. Fever continued. Blood examined for malaria plasmodia; none found. 19th, complained of some pain in belly; no diarrhea; tongue coated; spleen enlarged. 20th, bowels moved three times to-day; stools of yellowish-gray color. 22nd, marked diarrhea; some cough, bronchitis; typhoid condition. 27th, bloody stools. 28th, another hemorrhage from bowels. 29th, delirious; another hemorrhage; pulse weak. Temperature at 10 A.M., 40.6° C.; pulse, 156. Extremities cold; failing rapidly. Died at 1.20 P.M.

CASE XXVII.—Martin Crowley, aged twenty-two years; nativity, Ireland. Co. D., 7th Infantry. Wounded, July 1, 1898. Bullet entered right hip about four inches below superior spinous process of ilium, outer side, and passed diagonally downward but inward to inner side of thigh, upper third. July 16th, wounds of entrance and exit in fairly good condition. No pain. July 21st, some pain in thigh and further examination showed a slight swelling; pulsation, characteristic thrill, and bruit of aneurism; probably communication between femoral artery and vein. July 26th, wounds healed. July 27th, complained of diarrhea and later in day had a chill, followed by fever and malaria, for which quinin was given, with diluted nitromuriatic acid. July 28th, less fever; quinin continued. July 29th, better; temperature and pulse normal. August 3d, doing well; aneurism continues about the same.

CASE XXVIII.—Tobias Wunder, aged twenty-nine years; nativity, Germany. Sergeant, Co. G., 6th United States Infantry. Wounded in calf of the left leg, the ball going through the leg transversely and penetrating the skin and superficial fascia for about three inches. The wound became infected throughout its extent, an abscess forming. This was opened on July 18th and dressed antiseptically. Continued to discharge pus until August 1st, when the whole course of the ball was laid open, the necrotic tissue removed, and wound placed in condition to heal by granulation.

CASE XXIX.—Henry Brightwell, aged twenty-three years; nativity, Georgia. Co. G., 25th Infantry. While lying down during the fight of July 1st he was struck by a missile which caused a ragged, lacerated wound upon the outer side of the left thigh, five or six cm. below the trochanter major. No wound of exit. When he was admitted the wound was about four cm. long and suppurating freely, and he complained of pain in his outer thigh muscles when he walked. The X-ray revealed a bullet about fifteen cm. above the external tuberosity of the femur. On July 30th pain had become worse and localized, and a small incision was made, until the fascia lata was opened, through which was removed a bullet about the size and shape of an incisor tooth. A small piece of the steel jacket still clung to the wedge-shaped front of the lead bullet. Both wounds are doing well and the patient has no trouble in walking.

CASE XXX.—Winifred Munson, aged twenty-one years; native of Kentucky. Co. C., 6th Infantry. While charging El Caney, July 1, 1898, he was struck by a missile, which entered the sternum to the left of the midline, about the junction of the manubrium and gladiolus, making a clean, round hole without comminution, passing thence backward and to the right to an exit just below the neck of the scapula, the latter being a lacerated wound two centimeters in diameter. He advanced fifty yards and then sat down. A comrade removed his clothes, and blood came in "spurts" from the front, and continuously from the exit wound, and blood poured from his mouth. A first-aid bandage stopped external bleeding, after which he was neglected, being without food or attention until removal, thirty-six hours after, to the Division Hospital. For several days he spit fresh blood when he coughed, and this was followed by clotted blood. July 16th, before admission, he had a severe hemorrhage, losing fully 7 ounces. When admitted, July 16th, the entrance wound was about healed, and the exit was covered with granulations. His temperature was normal, but a cough without expectoration troubled him. The lung seemed to have only a slight diminution in function. On the 21st his temperature rose, and until August 1st remained between 38° and 39° C. (100.5°–102.2° F.); his respirations were rapid and painful, and there was dulness in the middle lobe of the right lung. About August 1st his temperature and other symptoms disappeared, and he improved. There appeared a pleuritic effusion, which reached the fifth rib in front and the inferior angle of the scapula behind.

CASE XXXI.—John K. Emery, aged twenty-three years; native of Georgia. Co. F., 13th United States Infantry. Wounded, July 1, 1898. Wound of entrance through the ensiform appendix of sternum; of exit in eighth interspace between anterior and mid-axillary lines. Course of wound was through the right lung. The injury produced hemoptysis, which lasted several days. Wounds of entrance and exit small, and healed rapidly. On admission he complained of considerable pain over

wound; examination showed slight pleurisy; side was strapped and condition improved. Since then has been steadily improving.

CASE XXXII.—Edward Culver; native of the Indian Territory. Troop A., 1st Volunteer Cavalry. Wounded by Mauser ball, on June 24, 1898. The ball entered the chest in fourth interspace in anterior axillary line of left side. No wound of exit. X-ray shows the ball lying across the 4th and 5th ribs of opposite side about two inches from vertebra. Both lungs were perforated, the ball going immediately behind the heart. The wound of entrance was about one inch in diameter, the ball having entered flatwise. Hemorrhage was quite profuse. Hemoptysis began at once and was also quite profuse; continued about fifteen days. Has been walking around since July 4th. Wound of entrance was packed with gauze; it granulated quickly and was completely healed on August 1st.

CASE XXXIII.—William F. Brewer, aged 26 years; native of Ohio. Company E., 17th U. S. Infantry. Concussion of brain and spinal cord by explosion of shell. Was making a charge when there was a violent explosion of a shell a few feet to left; was rendered unconscious and remained so about three hours. On regaining consciousness attempted to rise but vomited blood and contents of stomach, and could not support himself on left leg. Was carried to hospital at Siboney, and then sent North on the "Olivette." Had considerable pain all the time. Examination shows area of tenderness over lumbar region of cord and muscles of thigh and gluteal. Was confined to bed but improved slowly. Potassium iodid in 1-grain doses had little or no affect. Actual cautery was applied in several locations with great success, the function of leg being almost completely restored in about a week. Massage was painful at first but later was of some assistance in treatment.

THE WOUNDED BEFORE SANTIAGO.

[Special Correspondence of the MEDICAL NEWS.]

IN CAMP BEFORE SANTIAGO DE CUBA,
July 31, 1898.

ON the 25th of June last the Army landed at Baiquiri. Since that date the rapid succession of events, the fatigues and privations of an active campaign under extraordinary conditions have prevented literary work. From the date of landing until the fall of the city of Santiago de Cuba the troops were under a continuous strain of marching and fighting. For this labor the protracted delays after embarkation at Tampa had, I believe, to a considerable degree unfitted them. Two weeks on shipboard, on transports hastily improvised, had softened the muscles of the men, the majority of whom went to sea for the first time in their lives. But although the flesh had been somewhat weakened the spirit and temper of the troops had not been appreciably impaired. Immediately after the landing of the 2d Division the march on Santiago began. The route, a mere bridle-path overgrown with a tangle of luxuriant vegetation, led around the coast hills westward through the small harbor town of Siboney, which fell into our hands on the following day without a struggle. The Spanish garrison, surprised, lost no time in making a hurried retreat leaving much valuable property to fall into the hands of the Americans. On the march through the jungle many of the men fell out of ranks from heat and the overpowering sultriness of the air. No casualties occurred, however, as the men so disabled straggled into camp later in the cool night air.

On the following day the cavalry division, dismounted, took the lead, and first encountered the Spanish in considerable force posted on a hill overlooking a rocky cañon through which our men were advancing. Here the sharp action of San Quesada followed in which the regiment of "Rough Riders" and a brigade of regular cavalry suffered loss. The wounded in this battle received prompt first-aid treatment, often under fire, by their regimental medical officers, and, on the same day, were carried back to Siboney on litters by relays of troopers, and during the night the greater number of them were transferred from the extemporized receiving hospital on the beach to the transports designated to receive them. This proved to be a labor of difficulty, as, there being no wharf, all landings had to be effected by beaching the ship's cutters employed in embarkation. As in this action the enemy did not use artillery, the wounds of our men were all inflicted by the jacketed bullet of the Mauser rifle, a missile of .26 caliber, which caused small, clean-cut injuries without laceration or crushing of bone. Three days after the application of the Esmarch dressing to the slighter injuries, I am informed that the greater number of them maintained an aseptic condition. As regimental surgeons had taken the field without their medical and surgical chests no major operations could be done in the lines. After the transfer to the transport, where all facilities had been provided, this work was promptly begun, and permanent dressings applied. The number of the wounded requiring surgical aid footed up about one hundred. Litters for removing the wounded from the field in the absence of the regulation stretcher were built from saplings bound with strips of canvas over which shelter-tents and blankets had been stretched effectively. A man with a perforation of the liver and kidney thus transported reached the hospital-ship without further injury, a journey of five miles or thereabout. The prompt aid rendered the wounded on this occasion, and in general, their immediate removal from the battle-ground, doubtless prevented many fatalities. Of sixteen men sent down from the regular brigade on litters, including the one referred to above, all had survived at the date of their departure from the harbor for a Northern port.

KAPPA.

MEDICAL PROGRESS.

Volvulus of the Small Intestine.—THORBURN (*Med. Chronicle*, June, 1898) says that volvulus of the small intestine may not be so rare an occurrence as is generally supposed. The ease with which an intestinal coil can turn on itself would doubtless often produce the symptoms of strangulation were it not for the fact that it can in most instances untwist with equal facility. Treves has adopted the hypothesis of a temporary and spontaneously

reduced volvulus of the small intestine to explain those cases of acute intestinal obstruction, occasionally recurrent, which recover without surgical interference, but he has had no ocular demonstration of the accuracy of this supposition. Thorburn was called to operate upon a patient who suffered from acute intestinal obstruction with great prostration. He found just such an acute volvulus of the small intestine as Treves has presupposed, and it was untwisted almost without any manipulation. A stool followed this brief operation by about three hours, but unfortunately the patient did not survive more than nine hours. In two other cases mentioned by the writer there was gangrene of the small intestine without any assignable cause, and these were considered by him to be cases of volvulus. One of the patients died after an operation, and the other without operative effort having been made. All of the patients were men, and in all cases there was great prostration, and great pain.

Are There Germs in the Normal Puerperal Uterus?—BURCKHARDT (*Centralbl. f. Gynek.*, July 2, 1898) having noticed how often in a normal convalescence from labor the cervix was still open on the tenth or twelfth day, and that there was also at this time a yellowish-brown discharge mixed with bits of tissue, made a series of examinations to determine the bacterial condition of the puerperal organ. He found that the cervix was always open enough to admit the finger as late as the twelfth day, and that if it appeared not to be so, the constriction was apparent, not real, and disappeared if the body of the uterus was lifted up straight. The inner surface of the uterus he found smooth. It felt like a granulating wound, while the placental attachment was easily made out by its greater roughness. Examination of the fluid taken from the upper portion of the uterine cavity showed it to contain germs in thirteen out of fourteen cases. These were all patients who were making a good recovery from labor, without fever or other abnormal symptom. "The puerperal uterus," says this writer in conclusion, "must be looked upon as an open wound. In the first days after labor it is free from germs, but little by little they spread over its surface as they do over that of every other open wound, the cervix offering little resistance to their progress. An internal os which readily admits the finger can hardly be said to oppose the passage of a microbe. But at this period the condition of the inner surface of the uterus is such that no evil follows this microbial growth except under adverse circumstances, such as the retention of secretion."

Surgical Treatment of Duodenal Ulcers.—WANACH (*Arch. f. klin. Chirurg.*, vol. 56, p. 425) says that the perforation of a duodenal ulcer at a place where the gut is not covered by peritoneum gives rise to a retroperitoneal abscess which may remain for a long time unobserved. The purulent collection may extend upward to the neck, or downward to the inguinal region, breaking in the same situation as the usual psoas abscess. The favorite site for the perforation of such an ulcer, however, is the anterior wall of the first horizontal portion of the duodenum. The result is either an encapsulated or a general peritonitis. The encapsulation of such a peritonitis is not so favorable as the same process in other places, since the abscess does not usually stop there but goes on to the formation of a subphrenic abscess, which either before or after operation usually results in the death of the patient.

If a general peritonitis follows the rupture of the ulcer the determination of the origin of the inflammation is generally difficult. The usual mistakes are those of attributing it to an ulcer of the stomach, or to appendicitis, or of setting it down as an idiopathic peritonitis. If found and closed there is a good chance for the patient to recover, and the operator should, therefore, use all diligence to accomplish this end in obscure cases of peritonitis. Wanach mentions a case of his own in which he opened the abdomen supposing that he had to do with an appendicitis. Upon learning his mistake the real perforation in the duodenum was located, and closed by serous suture of the intestine and mesentery. The patient recovered.

Treatment of the Stump of the Appendix.—HAGGARD (*Jour. Am. Med. Assoc.*, June 4, 1898) finds that there is good reason for abandoning entirely the original practice of ligating the stump of the appendix. He says that it should not be treated as if it were a pedicle, but as if one were dealing with the end of the intestine, as in a lateral anastomosis. He therefore follows the practice of Deaver, which is applicable in cases in which the appendix is necrotic, as well as in those in which it is sound, and which is especially useful in cases in which it is changed into a dense cord. The details of the procedure are thus given: "After freeing the appendix from adhesions and meso-appendix, the cecum is stripped of its contents and grasped between the fingers and thumb of the left hand; the appendix being held up with forceps by an assistant, is then cut off flush with the colon. The rent at the site of its former junction is united by continuous Lembert sutures, just as in a gunshot or stab wound of the intestines, while the cecum is still held securely with the left hand. The sutures may be disposed in two layers, the first uniting the edges of the wound, the second approximating the peritoneal covering of the cecum over it."

Hernia of the Ovary.—BROWNE (*Maryland Med. Jour.*, July 9, 1898) reports two cases of hernia of the ovary. Both were inguinal in situation. Both patients had borne a number of children. In one case the ovary was irreducible, and the diagnosis was not made until the dragging of the cornu of the uterus into the opening of the hernial sac caused strangulation and rendered an operation necessary. In the other case the ovary was reducible, and the diagnosis was correctly made, but a truss failed to keep the displaced organ in position and operation was resorted to for the relief of pain. Laparotomy was performed upon both patients, and both recovered. The ovary which had produced strangulation was removed. The other was reduced into the abdominal cavity, and gave the patient no further trouble.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, AUGUST 13, 1898.

THE ARMY MEDICAL INVESTIGATION A FARCE.

GREAT chagrin and keen disappointment are being felt by all interested in the reputation of the medical arm of the service by the autocratic way in which the head of the War Department has dismissed the case of the transports "Seneca" and "Concho" which recently brought sick and wounded soldiers home from Cuba in a condition of wretchedness and neglect. Serious charges of incompetency and neglect of duty by the officers in charge of the commissary and medical supplies of the army of invasion at Santiago have also been made and the incompetency there shown has been charged in some quarters to lack of administrative ability on the part of the Surgeon-General of the army. In answer to these charges Surgeon-General Sternberg declares that he is not responsible and to vindicate himself and his subordinates demanded of the War Department an official investigation. This demand of General Sternberg has been met by the cavalier statement of the Secretary of War that in the transportation of the troops and in the campaign against Santiago there was no neglect and no incompetency; that hunger, sickness, and suffering are incidents of war and whatever has happened was due to unforseen circumstances and no one is to be held responsible.

Is no one responsible for leaving the medical supplies at Tampa when the transports sailed for Cuba? Is no one responsible for the fact that when the supplies did arrive off the Cuban coast they were not landed but carried back to Florida on the return cruise? Is no one responsible for the fact that while our soldiers on the fighting-line were without food and the ordinary comforts of a soldier's life a whole shipload of supplies was left rotting in the hold of a ship at anchor off the coast? Is no one responsible for the wholly unnecessary suffering, want, and hunger experienced by our wounded soldiers, so graphically described by our special correspondent in the MEDICAL NEWS of last week? Does the Secretary of War think for one moment that such flippant explanations explain anything, or satisfy the indignant but long suffering friends of the soldiers that these horrors will not be repeated? No.

Does he imagine that the thin coat of whitewash applied by his investigator Heyl over the "Concho" case can cover up the flat contradiction therein contained of well-attested facts, the avoidance of other charges or the implied confession of it all when he asserts that these abuses will not occur again?

Is General Sternberg going to be satisfied with this farcical procedure? We hope not—he owes it to himself, to his department, and to the army of faithful and efficient officers in the medical arm of the service that no part of this responsibility shall be allowed unjustly to rest upon the medical officers. The whole truth should be brought to light and responsibility fixed by a prompt, impartial, and searching investigation.

THE CAMP AT MONTAUK AND QUARANTINE.

THANKS to the harmonious cooperation of the Marine Hospital Service, the State Quarantine, and the Medical Department of the Army, a well-devised and systematic arrangement for preventing an invasion of yellow fever has thus far been entirely successful. Since the prompt and complete suppression by the Marine Hospital Service of the outbreak of the disease at McHenry, Miss., the weekly bulletins have announced that no new cases have appeared at any point within our borders. The number

of soldiers and civilians returning from Cuba has been comparatively few, and the stringent and impartial quarantine rules have been efficient in protecting every point of possible invasion. The bringing home of General Shafter's entire army, however, forces the yellow-fever question into unexpected prominence and necessitates a readjustment of quarantine rules to meet the new situation. Yellow fever, as existing in the army at Santiago, was at first extremely mild and the mortality slight, but in the daily reports from the front it is noticeable that the number of deaths from this cause is steadily on the increase, thus confirming the opinion of experts that the disease would become more fatal as the season advanced. It is certainly inevitable, in spite of the greatest care and supervision on the part of the inspection officers at the point of departure, that yellow fever will accompany this army in its removal to its northern camp. To detain the crowded transports at New York quarantine would not only be an act of cruelty but suicidal in the highest degree. It has, therefore, been decided by the Government to declare the camp at Montauk a quarantine detention-camp, and to send the transports directly there instead of allowing them to enter New York harbor. This decision is eminently wise, and dictated by every sentiment of humanity and consideration for the afflicted soldiers.

Previous to the issuance of the orders to bring General Shafter's army home, the cavalry regiments at Tampa and Fernandina had been commanded to move at once to Montauk Point. This order was promptly executed, and the troops were landed at their destination. The situation thus presented is a serious one, and the injustice of placing in one camp soldiers who have not been subjected to infection, and those who have, is apparent to the most casual observer. It can be safely managed, however, with proper attention to details. With sufficient distance, and an impassable barrier between the two divisions of the camp, reinforced by strict quarantine regulations, comparative safety may be secured. The handling and the storing of supplies unloaded from trains should be accomplished by a force detailed for this special work, and kept carefully free from infection. Supplies sent to the patients in the hospital camp should be distributed in packages, the containers of which can be promptly destroyed or easily disinfected. This refers to paper wrappers, potato-bags, milk cans, etc., etc.

Whatever arrangements the authorities may make to prevent the spread of infectious diseases among the soldiers confined in this camp, one thing is certain —that quarantine regulations should be sufficiently stringent to prevent their extension beyond the boundaries of the camp. The army at Santiago was inoculated with yellow fever by criminally allowing the refugees to intermingle with the soldiers and infect their ambulances and commissary wagons. The danger now is that as eager a horde of friends may invade the camp and kindle a widespread epidemic by bearing to their respective homes the germs of disease. The quarantine regulations for this camp cannot be too stringent for the safety of the country, and should be administered with the greatest circumspection and impartiality to the last detail.

It is a gratifying assurance to know that the Marine Hospital Service, whose officers have been especially trained in quarantine matters, are to have charge of the quarantine regulations connected with the transportation of the troops. Not only is a careful inspection to be maintained at the point of embarkation for the purpose of separating from the main body of the army cases of infection, but an officer of the Marine Hospital Service will accompany each ship for the purpose of assisting in isolating at once any case which may break out during the voyage, and personally direct the management of these cases upon arrival at destination, as well as to certify to the healthfulness of the ship. These officers aboard ship will have absolute supervision and medical control of the ship's crew, and lend such assistance to the army surgeon in charge as may be desired.

Administrative ability of the highest order will be required to efficiently enforce the quarantine regulations at Montauk. The management of this whole affair and the steps taken to secure the country against infection from this center of dissemination will be watched with a jealous and critical eye.

MODERN SURGERY IN WAR.

THE *British Medical Journal*, in a recent editorial upon this subject, announces the fact that it has been found possible to bring home some of the wounded troops from Egypt without changing the aseptic

dressings applied when the wounds were first treated. It regards this, and justly so, as a triumph of good surgery and good organization, and it proves that military surgery has shared to the full in the remarkable advances in surgical ideals and methods which the present generation has witnessed.

The editor then briefly reviews the advance in surgery from the former ideal, when it was the wish and gratification of the surgeon to have the dressings rapidly soaked with discharges from the wound, in the form of what was then regarded as "laudable pus." In the next stage of advancement chemical antiseptics were freely used for the purpose of destroying all forms of infective life as well as in directly irritating the wound to more abundant secretion. At the present time the highest aim of wound-treatment is to see that Nature is left to herself. As little as possible is done to wounds, whether by antiseptics or by manipulation, with the intent of securing a maximum of rest and a minimum of pain and fright to the patient. If by this means the wound is left clean and at rest, Nature will carry on the healing process to a successful issue.

In order that these principles of surgery may be put in force in the present campaign, the American soldiers were supplied with simple antiseptic bandages, to be applied at once to whatever wounds were received. It was hoped that this precaution, taken to prevent the access of bacteria and so preserve the wound in an aseptic condition, provided the missile or weapon did not carry infecting germs and distribute them in its course, might prove efficient in obviating the necessity for further surgical interference. The small-bore projectiles with their high velocity and clean-cut holes make simpler wounds and permit of this treatment reaching such a degree of perfection as to obviate the necessity of the wound being dressed for many succeeding days, and frequently to permit of its complete cicatrization without molestation. How far the application of this principle in the present war has prove successful, we shall soon learn. The inadequate supply of first dressings and the impossibility of securing complete rest to wounded parts by reason of the inefficient ambulance service due to impassible roads have marred greatly the value of observations along this line of enquiry.

The two cases of injury which occurred on board the flagship "New York" at the bombardment of San Juan, are impressive examples of the success of this treatment. In one case the bony structures of the elbow-joint were completely carried away by a fragment of shell, and in the second there was a compound comminuted fracture of the left femur. Both cases were promptly dressed asepticly by the fleet-surgeon, and complete rest secured for the members by the application of plaster-of-Paris dressings. In this condition the men were transferred to the ambulance-ship "Solace" and later placed in the naval hospital at the Brooklyn Navy Yard. Up to the seventh day the pulse, temperature, and general condition indicated that the healing process was going on satisfactorily, and the original dressings had not been molested.

INTESTINAL AUTO-INTOXICATION.

Intestinal auto-intoxication is a surgical condition which has been for the most part relegated to the field of internal medicine, and oftentimes in the conduct of his operative cases the surgeon, having placed it in this category, dismisses all thought of it from his mind. The principle of intestinal intoxication is familiar enough, and is regularly referred to by the bacteriologist, the pathologist, and the lecturer in surgery in illustrating an intoxication. Yet the surgeon allows its application in surgery to end here, and thereby may fail to bring under this classification a certain recent laparotomy case that is doing badly, a case where the pulse is still up on the third day, the temperature has reached 100° F., the abdomen is somewhat sensitive, the patient continues to vomit her food, and the bowels do not move. The post-mortem findings are slight, yet a reluctant diagnosis of peritonitis is made as a cause of death, and the surgeon is totally at a loss to know why his patient should have had peritonitis.

His patient is suffering from an intestinal auto-intoxication which passes over into a true sepsis, and the poison which overwhelms such a patient is not from without but from within the intestine itself. Secondary to a persistent reflex paralysis of the motor function of the intestine by shock and to an alteration in the intestinal function, there results both an increased production and a failure to eliminate toxic materials. Consequently the leucomains and the ptomain, or toxalbumin, products of the

putrefactive bacteria are absorbed into the circulation and transported to distant parts to overwhelm the system and produce the constitutional symptoms that have already been mentioned.

The intestine is often the seat of such a disturbed metabolic process apart from any operative procedure. Excretory products poisonous to the system are regularly formed in the intestine, yet normal, regular action of the bowels carries this away as excrementitious material without damage to the system. Should the regular excretion of this material cease, as in constipation or in intestinal indigestion, it is absorbed and gives rise to the usual symptoms. In post-operative enterosepsis, however, the intestine has not been satisfactorily emptied and added to the mere retention of toxic materials regularly formed, there is a paralyzed function, with a consequent increase in fermentative and putrefactive decomposition, a lessened intestinal antisepsis, and an increased absorption. The intoxication soon passes over into a true sepsis, and the patient's history is short.

The condition is recognized by most surgeons as a grave one when it arises, but the reasoning as to its origin seems to be bad, and refuge is too often taken in the comprehensive diagnosis of peritonitis. When the condition is better understood more care will be given to the preparation of the gastro-intestinal tract previous to operation, and less reliance placed upon the single cathartic. It is surprising that a subject of such importance should have no space in the text-books on surgery, and should appear so seldom in periodic literature.

ECHOES AND NEWS.

Sir William Broadbent Honored. — The Queen has appointed Sir William Broadbent, as one of her Majesty's Physicians Extraordinary, in place of the late Sir Richard Quain.

Dr. Voisin Dead.—The death of Dr. Auguste Voisin, Paris, physician to the Salpétrière Hospital, is reported. Dr. Voisin had long been one of the foremost authorities on hypnotism and mental diseases.

Memorial to Mr. Ernest Hart.—The Council of the British Medical Association has decided to found as a memorial of the late Mr. Ernest Hart, a scholarship, to be called the Ernest Hart Scholarship for Preventive Medicine. The scholarship, which will be of the value of $1000, will be tenable for two years.

Medical and Surgical Relief at Santiago.—It is reported from Tampa that the steamship "Michigan" sailed August 1st direct for Santiago. She carried twenty-five army surgeons, and fifty Red-Cross nurses for the hospitals. She had also on board 150 tons of fresh beef in addition to a large cargo of general provisions for the army.

House Cleaning in Santiago.—Under the direction of Governor Wood, the cleaning of the city of Santiago is being pushed with great energy. Before the door of every house lies a great pile of rubbish which has been dumped into the street awaiting transportation and final incineration. More than two hundred carts are employed in transporting the dirt and refuse removed from the houses.

The Disinfection of Mail at Siboney, Cuba.—Louis Kempner, acting postal agent at Siboney, Cuba, announces that when despatching mail to the States, he is obliged to certify to Major La Garde that fumigation of all pouches and sacks has been effected in accordance with the requirements agreed upon by Colonel Greenleaf, chief surgeon, U. S. A., Dr. John Guiteras, Major La Garde, and himself.

Sick and Wounded Soldiers Granted Furloughs.—The Secretary of War has directed that sick and wounded soldiers sent to the hospitals shall, when able to travel, be granted by the attending surgeon one-month's furlough and transportation to their homes. Experience in the Civil War demonstrated the fact that soldiers thus granted furloughs convalesce much more rapidly than when retained in hospital or confined in camp.

The Hospital Ship "Missouri."—Through the agency of Miss Helen M. Gould, the hospital ship "Missouri" will be supplied by the War Relief Association with four electric kitchens. This device will avoid the heat which usually comes from the ship's galley and thus contribute to the comfort of the sick and wounded. To avoid dampness on the ship, each deck will be covered with a coat of asphalt three-quarters of an inch thick.

A Medical Millionaire.—News has recently come from Paris that Baron Henri de Rothschild, a member of the Paris branch of the famous financial family, has passed with distinction his final examination for the degree of Doctor of Medicine. M. de Rothschild's graduation thesis is founded upon observations made in a private dispensary, which he established for the treatment of infants, and was awarded a silver medal by the Academy of Medicine.

Patent Medicine for Soldiers.—An enterprising patent-medicine vender in Brooklyn, N. Y., conceived the idea of distributing through the chain-letter scheme, a wholesale supply of his concoction to the soldiers at Santiago. The first links of the chain of letters requested each recipient to send 10 cents wrapped in tissue paper to pay for 10-cents' worth of the greatly needed medicine, and to make and forward to two other benevolent persons two copies of the letter. The medicine was to be distributed by the Red-Cross nurses, and the International Com-

mittee of the Y. M. C. A., although neither organization was privy to the scheme. Owing to the prompt action of the Brooklyn Bureau of Charities, this fraudulent enterprise was nipped in the bud.

Yellow Fever and Quarantine.—No case of yellow fever has as yet entered any of the ports of the United States, and it is positively announced by quarantine officials that no alarm need be felt lest fever may creep in, in bringing the sick and convalescent soldiers from Santiago. All transports bringing soldiers from Cuba are subject to the same quarantine regulations as other ships, and the pilots and masters of vessels are forbidden to dock their boats or drop anchor without a quarantine certificate. In evidence of this, five blasts of the whistle must be given before docking or dropping anchor, as a signal that the certificate is in possession of the master of the vessel. Moreover, the Marine Hospital Service has stationed at Cuban ports inspectors to certify to the fact that every ship leaving port is free from infection.

The Danger from Cuban Cemeteries.—It seems that those who die in Cuba are destined to secure the peace and quiet of sepulture only so long as they have paid for the niche in which they are destined to be deposited. "Rest in peace" depends upon the affection and willingness of the dead person's friends to pay another's rent in advance. When the year expires, unless the yearly rental is forthcoming, the coffin is unceremoniously taken out and dumped on a convenient field without the sacred compo. The walls of these niches become masses of germ-laden masonry alternately warmed by the tropical sunshine, and kept moist by tropical dews. In other words, they are most favorably culture-beds, and containing as they do the foul germs of yellow fever, become when disturbed sources of widespread infection. The disinterring of the dead is not allowed in Jamaica. Four years ago, in one of the West-Indian islands belonging to Great Britain, part of an old cemetery was dug up which contained the graves of many yellow-fever victims. Yellow fever had been absent from that island for years, but immediately after this it appeared and made many victims.

Tax on Proprietary Articles.—On July 7th the Internal Revenue Bureau prepared a circular for the instruction of collectors regarding the use of stamps required by schedule B of the War Revenue law. Its publication was suspended at that time to permit manufacturers of pharmaceutical preparations to present arguments why, under the last clause of section 20 of the act, there should be a modification of the rulings relating to those preparations. The circular was issued July 27th, and after quoting the part of section 20 referred to, says:

"This is undoubtedly entitled to peculiar weight as a legislative interpretation of that part of schedule B which relates to medicinal articles. This office construes said clause as follows: 'Any medicinal article which is compounded by any formula, published or unpublished,' will be held taxable under schedule B, act of June 13, 1898, when it is:

"(1) Put up in style or manner similar to that of patent, trade-mark or proprietary medicines in general; or

"(2) Advertised on the package or otherwise as (A) remedies or specifics for any ailments, (B) as having any special claim to merit, (C) as having any peculiar advantage in mode of preparation, quality, use, or effect."

Various exceptions are detailed, and the following recapitulation of the ruling is given:

"All medicinal proprietary articles and preparations must be stamped. All medicinal patent articles and preparations must be stamped. All medicinal trade-mark articles and preparations must be stamped. All medicinal articles compounded by any formula, published or unpublished, which are put up in a style or manner similar to that of patent, trade-mark, or proprietary medicines in general, or which are advertised on the package or otherwise as remedies or specifics for any ailment, or as having any special claim to merit, or to any peculiar advantage in mode of preparation, quality, use, or effect, must be stamped.

"All medicinal articles or compositions whatsoever, which, if prepared by any formula, published or unpublished, or held out to recommend to the public by the makers or venders or proprietors thereof as proprietary articles or preparations, or as remedies or specifics for any disease or diseases or affecton whatever affecting the human or animal body, must be stamped."

CORRESPONDENCE.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

VIRCHOW ON TABES, SYPHILIS, ETC.—THE CONGRESS OF SCIENTIFIC INVESTIGATORS AND PHYSICIANS—A NEW SECTION—A LEGAL VICTORY FOR THE SELLERS OF SECRET PREPARATIONS—ARTIFICIAL FOOD PREPARATIONS AND TESTS FOR THEM WITH ANALIN COLORS—THE PRUSSIAN INSTITUTE FOR THE PASTEUR TREATMENT OF RABIES OPENED—LEYDEN'S ELECTION AS CORRESPONDING MEMBER OF THE INSTITUTE OF MEDICINE, PARIS, AND OPINIONS THEREON.

BERLIN, August 2, 1898.

AT the close of a recent discussion of tabetic optic nerve atrophy at the Berlin Medical Society, Professor Virchow, who almost never misses a meeting of the Society, of which he is president, took occasion to express his views on the etiologic connection between syphilis and tabes. He has very little sympathy with the opinion now so common all over Europe that tabes is practically always the result of syphilis, and seems to think that the two diseases are connected together by no closer bond than that of mere coincidence. Syphilis is common enough anyhow, but when a patient's history is taken almost with the persuasion that syphilis is to be found in it, then it is extremely easy to light on some dubious, suspicious statement of an unwitting patient who does not realize how significant his slightest expression may be taken to be, and make it a peg on which to hang a syphilitic anamnesis.

There are other pathological conditions which it has

become the custom to attribute to syphilis, aneurism, for instance, yet it is extremely rare to find an aneurism in a tabetic subject. Amyloid degeneration of the organs is so often connected with syphilis that the pathologist always looks for it in subjects that have been syphilitic, and finds it very often. Yet amyloid degeneration is not found oftener in subjects affected by tabes than in others. The so-called amyloid bodies of the cord that are sometimes found in old tabetics are not connected with genuine amyloid degeneration, and are only the expression, it would seem, of a sort of senile evolution.

It is now with syphilis as it was formerly with malaria; when the latter disease was very common it got to be the custom to attribute a great many pathological conditions to it. At present syphilis has become very common, and so not only tabes and general paralysis, but all the constitutional diseases whose origin is as yet obscure, are attributed to it. Leucemia, formerly thought to be surely post-malarial, now comes under the head of post-syphilitic. Diabetes mellitus and pernicious anemia share the same fate.

There is certainly not sufficient demonstration of the connection between tabes and syphilis, in Professor Virchow's opinion, to justify antisyphilitic treatment in the nervous affection. The jumping to therapeutic conclusions on grounds as insufficient as exist in this case smacks of the purest empiricism, and cannot be considered rational therapy. It is all the more to be deprecated since antisyphilitic treatment, if persevered in for any length of time, cannot but be productive of harm in the sclerotic process that has already invaded the central nervous system.

The next meeting of the German Scientific Investigators and Physicians will be held at Düsseldorf from the 19th to the 24th of September. This is the seventieth annual meeting, and its proceedings may be expected to be as interesting as they always have been, this being the favorite occasion for the announcement of medical discoveries made during the year. Despite Professor Edinger's letter of last year and the discussion of the question of dividing up the interest of the sessions by the creation of further special sections, a new section, that of the history of medicine, is to hold its first sessions this year. The section evil in medical-society meetings has come to be looked upon as inevitable, and so its progress, still further specializing all the information a doctor may get at such assemblages, goes on advancing from year to year untrammeled.

After having demonstrated some time ago at the Hufeland Medical Society that the anilin dyes as used in bacteriology would probably serve as useful tests for the organotherapeutic preparations, Professor Posner has now extended the sphere of his observations in this line, and made it include the artificial food preparations. Color reactions for starch and fat were in general use before definite color reactions for albuminous bodies would seem to be possible with the Biondi triple stain and with certain of the Ehrlich stains. Professor Posner proposes to continue the series of investigations in the hope to be able to supply the practitioner with a ready method of deciding whether an artificial food preparation really contains the ingredients claimed to be in it by the manufacturers, and whether they are present in the amounts claimed without recourse to chemical analysis. Professor Posner is especially of the idea that this method may enable physicians and apothecaries to decide whether samples of the preparation delivered at different times contain the same ingredients in the same amounts as were present in the original samples. The microscope is necessary for the decision of the question, and the specimens prepared may be kept as microscopic specimens generally for reference and comparison.

A recent decision of the German courts with regard to what are called secret preparations, the equivalent of our term patent medicines, seems of interest. It is considered in a certain sense a victory for the patent-medicine people, since it asserts the illegality of the police regulations that are not founded on the wording of the law regulating the selling of drugs by apothecaries. Apothecary shops are, however, in Germany distinctly a State institution; only one is allowed to occupy a certain district, and the prices of drugs are regulated to the minutest details, there being a whole series of prescriptions containing most of the drugs in ordinary use, which the apothecary must make up for the poorer classes at prices fixed by law, and in all cases there is a limit to the charges which may be made for any given amount of a drug and for its incorporation into a prescription.

The court reasserts in explicit terms the regulations to which apothecaries are already subjected by law, and it would scarcely seem that additional police ordinances were necessary. They are permitted to sell only remedies the ingredients of which are absolutely and definitely known to them. They may not sell a remedy, unless on prescription from a doctor, that contains any drug ordinarily not allowed to be sold without a prescription. (This includes some drugs that are ordinarily not considered to be poisons but still dangerous if allowed to be procured promiscuously, as chloral, cocain, and antipyrin.) Finally, all remedies must be sold at prices that do not exceed the limit of price set for their separate ingredients in the amounts dispensed by the laws regulating the sale of drugs. If a legal victory for the patent-medicine people in America could only lead to the reassertion of some such thoroughly sensible regulations as these I think that there are those in the profession who would be ready to begin the suit at once. Meantime, however, American legislators seem not to have the slightest inkling that great frauds are being perpetrated openly on the public, and that there is practically a conspiracy between manufacturer, seller, and advertiser to make the dear public pay for its whistle if he will have it in the shape of a worthless but much praised remedy.

During July the Institute for the Treatment of Rabies according to Pasteur's method, for which, as I stated some time ago, a special item was put into the budget of the Prussian appropriation for medical matters for this year, was opened. It is in connection with Professor Koch's institute for infectious diseases at the Charité, and individuals bitten by rabid or suspected animals are to be

treated free of charge. Where the rabies of the animal that has bitten is not clear the treatment is given only at the patient's request. According to the local papers, there were five deaths from hydrophobia in Prussia during 1897, of whom 2 were veterinary surgeons. As the Prussian East Sea (Baltic) provinces extend to the Russian line, this is not many considering the reported frequency of the disease in Russia.

The profession here in Germany has received with every mark of appreciation the recent honor conferred upon Professor von Leyden in his selection as corresponding member of the French Institute of Medicine. There are but eight corresponding members altogether, of whom, until his elevation some time ago to the rank of associate of the Academy of Medicine, Professor Virchow was one. Professor von Leyden succeeds to Professor Virchow's place. It is at once a high compliment to Leyden personally, and all the more so as his work has been almost entirely in the line of clinical medicine, for scientific honors do not usually come easily to clinicians, but to the lights in the theoretic branches of medicine, but the selection is more than a personal honor. As Professor Bonchard in Paris puts it, it is a mark of the high appreciation in which German medical authorities are held by French medical men, and a sign of the better feeling between the two nations that is coming as the result of the friendly relations of the rival scientists of the two countries.

GLYCOSURIA DUE TO SOMATOSE—PNEUMOTOMY FOR GANGRENE OF THE LUNG—CONGENITAL ICHTHYOSIS—FATAL ULCERATION OF THE STOMACH AND SMALL INTESTINE OF UNKNOWN ORIGIN — ERYSIPELAS FROM EMPYEMA — SERUM-THERAPY OF MUSHROOM POISONING—LIVING GERMS IN LIQUID AIR—PROPHYLACTIC MEASURES FOR TUBERCULOSIS ADVOCATED BY THE ACADEMY — TREATMENT OF ERECTILE TUMORS BY INJECTION— CYSTOCOLOSTOMY FOR EXSTROPHY OF THE BLADDER — ABDOMINAL EXTIRPATION OF CANCER OF THE RECTUM.

AT the Medical Society of the Hospitals, June 17th, RENON said that he had had occasion recently to prescribe for a nursing mother, aged forty, of a neurotic type, who after a slight attack of influenza found her milk rapidly diminishing. He ordered somatose with the happiest result, as within a few days the milk was present in abundance. Three weeks later while somatose was still being taken the infant refused the breast. The urine of the mother was found to contain a considerable quantity of sugar. The somatose was discontinued, and the glycosuria ceased at once, as did lactation. Since the glycosuria did not exist before the administration of the somatose, and disappeared with its withdrawal, the conclusion that it was produced by it, seemed unavoidable. It has also been noted by Drews and others that preparations of albumose, especially somatose, are capable of producing glycosuria. And it has also been observed that the amount of sugar in the urine of diabetics, is greatly increased if large quantities of meat are ingested. If glycosuria in lactation is due to the formation in the breasts of more sugar than can be utilized, and is therefore secreted by the kidneys, its presence in the urine of this patient would simply mean that she had received more somatose than was indicated. At any rate the case is of interest as showing one of the dangers attending the use of this class of remedies, and one of the methods of keeping watch of their action.

LE GENDRE said that he had never observed glycosuria to follow the administration to nursing mothers of somatose, and since glycosuria was by no means uncommon during lactation, he thought that other instances of the occurrence of glycosursia after the use of somatose should be reported before the conclusion could be accepted that the drug was the cause of the appearance of sugar in the urine.

GALLIARD related the history of a patient upon whom a pneumotomy was performed for pulmonary gangrene. The patient was a man, aged fifty, whose expectoration was fetid, and in whom the physical signs pointed to a gangrenous focus in the center of an area of hepatization in the lower portion of the right lung. A hollow needle was introduced, but nothing but a little blood was withdrawn. Nevertheless, on the following day, parts of two ribs were resected, and the underlying lung was pierced by a cautery-point. The point opened at once into a focus of gangrene, and pus and bits of disintegrated pulmonary tissue escaped. After the operation, the fetidity of the sputum disappeared, but a fever which had not before existed set in, and the patient died in nine days. At the autopsy a purulent collection was found above the right side of the diaphragm, which had escaped observation, and there was besides, a pericarditis and a hypertrophy of the liver. Both lungs were thickly studded with tubercles.

NETTER said that whatever might be the effect of surgical interference upon pulmonary gangrene, thoracotomy was disastrous in the presence of dilated bronchi. Since it is not always easy to diagnose this condition, and since there might be besides multiple foci of gangrene, one ought, to say the least, to be guarded in his prognosis of the results of a pneumotomy for gangrene of the lung.

June 24th, THIBIERGE presented two patients aged respectively eighteen and fifteen years, the condition of whose skin suggested ichthyosis. It was especially thick in the articular folds. There was considerable hyperkeratosis and slight hyperidrosis of the hands, while the skin of the face was retracted, and there was marked ectropion, characteristics which served to differentiate the cases from true acquired ichthyosis. In both of these patients the lesions were congenital, though there was no history of similar trouble in either of their families. For these reasons the lesion was looked upon as a cutaneous malformation, to which the name of congenital ichthyosis is sometimes given, and which is often fatal at an early period of life.

At the Session of July 1st, LE GENDRE showed the stomach and intestines of a patient whom he had treated for some time, supposing him to have typhoid fever, al-

though the serum reaction was always absent. No other lesions were found at the autopsy, except numerous ulcerations of the mucous membrane of the stomach and small intestine, and which grew fewer the farther one proceeded toward the ileocecal valve, contrary to what one observes in typhoid fever. Most of them were situated in the duodenum, and only a few were in Peyer's plaques. The mesenteric glands were sound. The bacterial examination of the organs was reported at a later session. It showed a total absence of the typhoid bacillus as well as that of anthrax. There were found both in the ulcerations and in other organs, the colon bacillus, and a long bacillus of putrefaction, but as the autopsy was not made until twenty-four hours after death, the presence of the colon bacillus could scarcely be said to be the cause of the lesions.

MENETRIER reported July 8th, the accidental contraction of erysipelas from the pus of a purulent pleurisy. The operator in this case scratched his ear with his finger-nail, causing it to bleed. The following day erysipelas developed and spead over a part of the face and neck. An interesting point in connection with the matter was that the pus was found to be harmless to animals which were inoculated with it. But it has before been observed that streptococci which are without effect upon animals are sometimes capable of causing erysipelas of a virulent type in man.

At the Biological Society, June 18th, CLAISSE pointed out that there are two poisons which affect most of the persons who are injured by eating mushrooms. One, muscarin, acts quickly as a powerful gastro-intestinal irritant, but is rarely fatal. The other, phallin, acts more slowly, so that it may be twelve, twenty-four, or even thirty-six hours, before the choleraic symptoms which it produces manifest themselves. Poisoning by this substance is usually followed by collapse and death. It is chiefly found in the variety of mushroom called *Amanita phalliodes*. Claisse expressed the idea that it might be possible to develop a serum-therapy for poisoning by phallin, just as has been successfully accomplished for poisoning by other vegetable substances, such as racin, venin, and abrin. His experiments upon this subject have not yet been finished, but, he had found that both guinea-pigs and rabbits are extremely sensitive to phallin if it is injected subcutaneously, although they can eat it without any ill effects.

At the session of July 9th, D'ARSONVAL stated that he had found that immersion for seven hours in liquid air, of tubes containing the bacteria of yeast, diphtheria, and blue pus, in no way affected their virility. Other germs were mixed with the liquid air and kept at a very low temperature (—275° C.) for six days and nights without losing in any way their power of growth and reproduction. Neither did the exposure to this intense cold for long periods, affect, in their action upon living animals, the products of these bacteria, diastase, toxins, etc. Possibly there is produced around the germs an isolating envelope, which protects them from the effect of this great cold.

At the Session of June 28th, the Academy of Medicine adopted the report of its Committee on the Prophylaxis of Tuberculosis, also making the committee a permanent one.

Destruction of Tubercle Bacilli. — 1. The Academy confirmed its action of 1890, by which three prophylactic measures were advocated, *viz.*: (*a*) The collection of sputa in a pocket or vessel containing a little colored, five per cent. carbolic acid, or at least a little water; (*b*) the avoidance of dust by substituting wiping with a moist cloth for sweeping; (*c*) the boiling of milk before drinking it, no matter what its source. It was further recommended that the premises be disinfected after the death of a tuberculous patient, or even after a short sojourn by such a one. His personal effects, bed, etc., should also be disinfected.

2. Concerning the family the Academy recommended the continued practice of defensive measures from the time that tuberculosis becomes "open." It advocated as far as possible keeping pulmonary tuberculosis in a "closed" condition by an early diagnosis and suitable treatment.

3. In the army temporary restrictions should be placed about one in the first stage of the disease, while those whose sputa already contain Koch's bacilli should be under permanent surveillance.

4. In every school, store, and workshop the one in charge should be instructed in the few simple rules which are sufficient to limit the spread of this disease and should be held accountable for their observance.

5. The Academy recommended with reference to the hospitals: (*a*) The separation of tuberculous patients in their own wards and the establishment of special sanitaria for them; (*b*) Antisepsis in both general and tubercular wards, especial care being taken to suppress sweeping and in the washing of dishes. (*c*) The improvement of the character of attendants.

6. The Academy approved of meat inspection, but thought the total destruction of meat was unnecessary except in the comparatively rare cases in which the flesh of the animal is infected with tubercles, and there is fever. Stock-raisers were advised to use the tuberculin test to mark for speedy slaughter animals which have become infected.

Maintenance and Increase of the Powers of Resistance of the Organism.—The measures under this head related chiefly to the treatment of soldiers. It was advocated that they should be given greater air space, a more nutritious diet, and that enlistment, maneuvers, and changes of garrisons should be made as far as possible under favorable climatic conditions.

At the Session of July 15th, ANGER described the treatment of erectile tumors by the injection of solutions favoring coagulation. The fluid which he preferred for this purpose is composed of twelve parts of water, three parts of sodium chlorid, and five parts of tincture of the perchlorid of iron. From two to forty drops are injected in one or more places, according to the size of the tumor. This injection is not at all painful. It is made if possible into a vein. To determine with certainty that the needle is in a vessel, Anger uses a double

needle, inserting the first in various places until the blood flows out of it, and then making the injection through this needle by inserting into it the point of the smaller needle on the syringe.

One thing is very important, namely, to make firm pressure all around the tumor, as with a ring, for a few minutes during and after the injection, until firm coagulation shall have prevented the passage of clots, or the solution into the circulation. Palpation with the finger will show when the clot is firm. The tumor will swell for two or three days, and then gradually diminish in size. At the end of three or six months the injection can be repeated if necessary.

Tuffier presented at the Session of July 12th, a young man upon whom he had successfully performed a cystocolostomy for exstropy of the bladder. The patient had several times been subjected to a plastic operation without success. The bladder was separated from the surrounding tissue sufficiently to allow the implantation of the trigonum in the sigmoid flexure, the openings of the two ureters being included in the piece thus transplanted. The wound healed well, and four months after the operation there was no inconvenience to the patient other than the necessity of a stool five or six times a day. The abdominal wound had completely closed.

At the Surgical Society, June 22d Michaux spoke of choledochotomy with suture. He had performed this operation four times, and the successes thus obtained led him to dissent from the views recently expressed in favor of leaving the duct to granulate without suture. Doubtless if the operator foresaw an unpleasant result from a suture in a given case it should not be performed; and in other cases perhaps suture was impossible; but with these two exceptions, he advocated the suture of the duct, which he had not found as difficult as some have said.

At the Session of June 29th, Quenu said that he had formerly held the opinion that cancer of the rectum if low down should be extirpated by the anal route; if in the middle portion, by the sacral route, and if of the upper portion, by the abdomino-perineal method. Experience had inclined him more and more to the last-mentioned method, rather than to the sacral one, until now he had given the latter up entirely. Two objections have been made to the abdomino-perineal method. One is the formation of a permanent iliac anus, and the other is the gravity of the operative attempt. It has not yet been definitely settled, however, that an iliac anus is worse than a sacral one. As to the gravity of the operation, that cannot be denied, but there is reason to believe that with practice the mortality will be reduced until it shall not exceed that of extirpation of the uterus for cancer. Two conditions are essential to success: asepsis, during and after the operation, and control of hemorrhage. The first object is obtained by the closure of the anus in the beginning of the operation, thus enabling the operator to treat the rectum as a sterile tumor, until its removal; while the loss of blood is avoided by the ligation of both internal iliac arteries.

The first step in the operation proper is a median incision and the ligation of the internal iliacs. Before these ligatures are drawn tight, the pulsation in the external iliac is felt for, to make sure that it has not been included by mistake; if enlarged glands are present they are removed. Next, the intestine is divided with a cautery between two ligatures, and its upper end is fixed in a short incision to the left of the median line. The whole lower portion of the bowel is next freed from its mesorectum, the superior hemorrhoidal vessels tied, etc. The last step of the operation is the removal of the rectum thus freed through the perineal wound, and the closure of the abdominal wound. The perineal wound is left open, with a tube and gauze for drainage.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

Sixty-sixth Annual Meeting, Held at Edinburgh, July 26, 27, 28, and 29, 1898.

THE PRESIDENT'S ADDRESS.

The opening address was delivered in McEwan Hall by the President, Sir Thomas Grainger Stewart of Edinburgh. He extended a cordial welcome to the Association and its guests, and expressed his high appreciation of the honor conferred upon him by his election to the presidency of the Association. He spoke of those members who had been removed by death during the past year, and paid a warm tribute to the memory of Mr. Ernest Hart, for so many years editor of the *British Medical Journal*. He then said that although the science or art of medicine has made enormous strides during the past few years, the members of the profession realize only too well its limitations and how far short it falls of an ideal. As an indication of the better understanding of causation and treatment it is only necessary to remember that since 1855 the annual death-rate in England and Scotland has decreased by more than one-fifth. Due to the efforts of the profession, too, tuberculosis is not the dread disease of thirty years ago, for carefully gathered statistics show that deaths from this cause have, during the interval, decreased by one-third. The public is gradually becoming educated to the importance of precautionary measures, and there is every reason to think that, from present appearances, as the years go by, the disease will become less and less common.

Referring to the attitude of the medical profession toward the national legislature, the speaker said that its duty is evident and should be exercised at all times toward the enactment of laws looking to the preservation of the public health. While, in their way, penalties for non-observance of health laws are well enough, the effort to instruct the people in all that pertains to the well-being of themselves and their children should be unremitting, for it is by such means that legislation will accomplish the greatest good. Willingness on the part of the laity to accept sanitary legislation, and to live up to its requirements, is based upon a proper understanding of just what these measures are to accomplish. Furthermore, legislative bodies should be educated to accept the advice of

recognized medical and sanitary authorities in the framing of laws designed to preserve the health of the people, in exactly the same way that they are biased by military or legal opinions in enacting laws in these departments.

He then called attention to the strong antivaccination movement in Great Britain, referring especially to the recent legislation on this subject in Parliament and to the statement by one of the minority members of the Parliamentary Committee to the effect that compulsory vaccination in Great Britain is dead and will remain so during the next generation. According to the bill introduced in Parliament during its last session, any person "conscientiously objecting" to vaccination may, by stating his objections before two examining magistrates, be made exempt. The speaker condemned this bill in unmeasured terms and referred sarcastically to the latitude allowed these faddists, who, from a sense of ignorance, are constantly endangering their own lives and those of their families.

Every effort should be made to extend our knowledge along the lines of advance and improvement. In every branch of medicine and the allied branches investigation is the order of the day, and at the present moment there is not a recognized medical center in the world wherein original researches are not being made. Empiric medicine and theories are largely things of the past, and while they well served their turn, the foundation laid upon them has resulted, and daily is resulting, in a broad and solid structure which is destined to grow and increase until such time as the last shadow of doubt will have disappeared.

While medical education in Great Britain has made great strides during the last few decades, it is to be regretted that the tendency still is to overburden the memory of the student with unnecessary details. All medical teachers should endeavor to instil the importance of mastering methods, rather than theories, and the curricula should be shaped to this end. Successful medical teaching can never be carried on except in connection with a great hospital, and bedside instruction, as now practised, should not only be continued, but amplified to the greatest possible degree. It is to be regretted that adequate facilities for post-graduate study have not yet been provided by the larger schools, but there is every reason to hope that this branch will be attended to in the near future.

The speaker then referred to the exceedingly satisfactory growth of the Association and to the good it had accomplished, and then spoke at some length upon the National Department of Public Health, suggesting where and in what manner radical improvements might be made. In conclusion, he again touched upon the relations which should exist between the physician and the public, and said that only when self is buried, and real or imagined wrongs put entirely in the background, will the science and art of medicine be given the recognition to which it is so justly entitled.

ADDRESS IN MEDICINE.

This was delivered by DR. THOMAS RICHARD FRASER, and was confined to an exposition of the advance which has been made along various lines since the Association met in Edinburgh twenty-three years ago. At that time, Dr. Warburton Begbie, who delivered the address in medicine, took for his subject, "Has the Practice of Medicine Made a Single Step in Advance since the Time of Hippocrates?" and answered the question in the negative. Since the date of Dr. Begbie's address, the speaker said, it cannot be denied that the steps forward have been many. Although so few years have elapsed, the increase in knowledge of the fundamental principles of chemistry, physiology, and morbid anatomy; of pharmacology, symptomatology, and diagnosis; of etiology and of treatment has been so great that the practice of medicine has been wholly removed from that empiric domain in which it rested during the lifetime of our predecessors, and now has reached that height where it may well be considered a science rather than an art.

After a warm tribute to those pioneers in the profession, whose work cleared the way for the present generation, the speaker referred to the instruments now in use—the hemacytometer, sphygmograph, and ophthalmoscope—which have so aided the diagnostician, and not only simplified his work, but placed it in a category from which mere guesswork has for all time been eliminated. Chemic examination of stomach contents and of the urine has also advanced the understanding of pathologic conditions to a marked degree, and the X-ray, though its application to injury and disease is yet in its infancy, has already proved a valuable adjunct to clinical diagnosis.

The ability to arrest and sometimes cure certain of the diseases of the nervous system, through the recognition of the fact that the etiologic factor is largely the presence in the body of toxic substances is most important, and the new doctrine is day by day being strengthened by the results of new investigations. The study of mental disease, too, has received a strong impetus recently through acceptance of the theory advanced by such well-known pathologists as Nissl and Van Gieson, that auto-intoxication from the intestinal tract is largely instrumental in their production. While further investigation must follow along the lines of the theory that auto-intoxication through the medium of a toxin contained in malignant growths is the factor principally concerned in the cachectic symptoms and fatal termination, rather than the degenerative processes in the tissues, *per se*, the work that has already been done in this direction is most encouraging, and there is every reason to hope that it will result in more perfect methods of treatment in the near future.

Bacteriology, of all the branches of medicine, however, has yielded the greatest discoveries. Only a few years ago it was universally accepted that the pathologic action of microbes in the system was due to their collection in the blood-vessels; or, perhaps, to their morbid action upon the products of digestion, thus robbing the tissues of necessary nutrition. The discovery of the complex poisons, or ptomains, which pathogenic germs give rise to in the body, however, and a careful study of the structural changes produced thereby, has revolutionized old theories, and placed this doctrine of toxic origin of in-

fectious disease upon a foundation which further investigation and study will render unassailable.

Closely following these discoveries it became known that under certain conditions it was possible to immunize the individual to the effects of these bacterial toxins, a fact holding close relationship to that so well-known, that one attack of certain of the infectious diseases confers immunity from subsequent attacks of the same malady. From this point serum-therapy has advanced along well-defined lines, and new methods and new discoveries are constantly being published by intelligent investigators throughout the world, so that scientific interest has been aroused to that extent that it is paralleled by no other discovery in the realm of medicine.

The speaker then somewhat minutely recapitulated the known conditions governing immunity against pathogenic infections, and ended by saying that even though much is to be expected from the action of serum-therapy, it will be necessary to more completely understand and control disease-producing germs before it will be possible to obtain serums of relatively equal immunizing power to the lymph used against smallpox.

ADDRESS IN SURGERY.

This was delivered by Mr. Thomas Annandale of Edinburgh, his subject being "The Present Position of Surgery." He considered it from three points of view—scientific, practical, and moral, and under the first head referred chiefly to the advances made in antisepsis. While the principles of this branch of surgery are now well established and understood, it is to be remembered that pathogenic organisms enter the body through other channels than breaches of the surface, and in consequence of this bacteriology rises to a point of great importance in connection with the results of injuries and surgical procedures. It has been shown that the ill effects are due to the toxins produced in the tissues by these micro-organisms, rather than to the specific action of the germs themselves. The study of physiologic chemistry and the application of its results undoubtedly will do much to throw light upon processes which as yet are unknown to us, thus allowing of a form of treatment which will be based upon sound scientific grounds. Until the origin and behavior of the various toxins have been learned, the application of antitoxin principles must necessarily be largely empiric. The subcutaneous injection of so-called antitoxic serums in connection with surgical procedures has met with uncertain results. In the speaker's own experience he had known of a number of patients to recover under this form of treatment from severe attacks of septicemia, while other patients, exactly as ill from the same cause, had recovered without such measures having been taken.

The question of the physiologic relation between different organs and tissues is also a matter which should be carefully studied. The relationship existing between the ovaries and the breast, for instance, possesses great interest to the surgeon. Acting upon this suggestion, he had removed the ovaries in three instances from women suffering from inoperable cancer of the breast, and while the disease was not cured, the removal of these organs markedly influenced the local breast condition for the better.

The use of thyroid extract in the treatment of myxedematous conditions has resulted in great benefit in many cases, and while this form of organotherapy has resulted in many disappointments, there can be no question that future developments will be productive of much good. The method of injections of the mixed toxins of streptococcus and prodigiosus in the case of malignant growths give rise to the hope that much good will ultimately result from this procedure, but it must not be forgotten, when reading the favorable published reports of these cases, that sarcomata and other growths occasionally decrease in size and even disappear without apparent cause. It is impossible to assign any reason for this decrease or disappearance except that of physiologic or bacteriologic change beyond our power to understand.

Under the second head of his address the speaker said that the best definition which characterizes the practice of surgery at the present day is *simplicity*. Leaving out the question of asepsis, which, of course, is taken for granted, this simplicity includes the technic, the instrumental assistance, and the after-treatment. As opposed to the surgery of even a decade ago, the effort and aim now is to leave as much as possible to Nature. It has taken a long time for surgeons to appreciate the importance of this step, but now that they have learned their rôle, the results have fully warranted their position.

Modern surgery has advanced also along the lines of expansion, to say nothing of the increased number of those who practise it. Delicate operations, which a few years ago would have been deemed impracticable or impossible, are now performed, and with the happiest results. The line which formerly was drawn between the duties of the general and the gynecologic surgeon has now almost disappeared, for it is appreciated that the training necessary to produce the one is equally applicable to the production of the other.

With regard to anesthetics, in the opinion of the speaker, chloroform continues to be the safest and most satisfactory agent in connection with surgical operations, but it should be administered only by a competent, well-trained anesthetist, and its effects should be carefully watched.

In treating of the moral aspect of surgery of to-day, the speaker said that while it is lamentable that the high standard which it so necessary for the members of the profession to set for themselves is ignored by many, the true cause of the evil can be traced to three factors: (1) Active competition, (2) untrained specialism, and (3) society demands.

Section on Obstetrics and Diseases of Women.

First Day—July 27th.

The President's address was delivered by Dr. Alexander Russell Simpson. He welcomed the members and foreign guests in behalf of the oldest chair of midwifery in the world, it having been established in 1726. He then spoke at some length of the history of midwifery

and its advancement, and of the very important part it plays in general practice. Many forms of disease may come and go, but midwifery goes on forever. He said that it receives but little attention in the schools as compared with that given to medicine and surgery, and that he hoped soon to see it occupying the position it deserves.

PROFESSOR W. S. PLAYFAIR of London proposed a vote of thanks to Professor Simpson for his address, and said that he agreed with him thoroughly in regard to the teaching of obstetrics. He had always been teaching obstetrics, and had insisted on the inadequacy of the teaching and had tried to bring about a reform in that respect.

PROFESSOR MARTIN of Berlin seconded the motion, and said that he considered it of utmost importance that every physician should be well fitted for obstetric work.

DR. CULLINGWORTH of London then opened a discussion on

THE SURGICAL TREATMENT OF PELVIC INFLAMMATION.

He discussed the following points: (1) The indications for operative interference in pelvic inflammation; and (2) the choice of time for operation. Under the first head he first spoke of pelvic cellulitis. If unattended by suppuration no interference is necessary; when an abscess has formed, the pus should be evacuated as soon as it is discovered and is within reach. The indications in pelvic peritonitis cannot be stated so categorically. The personal experience of the speaker has led him to regard the following signs and symptoms as being strongly suggestive of the need for operative interference: (*a*) The presence of a definite, more or less fixed, irregular swelling in one or both posterior fossæ of the pelvis, larger than could be accounted for by a thickened tube matted together with a normal ovary. If this increases in size in spite of local treatment, the suspicion of pus gives way to certainty. (*b*) The occurrence, during an attack of acute inflammation of the uterine appendages, of a tense globular, cystic mass in the pouch of Douglas. (*c*) The outbreak of recurrent attacks of pelvic peritonitis in a patient known to have had an acute salpingitis, in whom there has remained a quiescent but obvious swelling in the posterior part of the pelvis. (*d*) The sudden appearance of symptoms of general septic infection in a patient with a more or less definite history of pelvic inflammation and a localized swelling above the vaginal roof. Such cases urgently need surgical intervention. In non-suppurative inflammation interference is indicated if there is reason to fear complications or if the circumstances of the patient are such that it is necessary to restore her to health quickly.

With regard to the choice of time for operation, it is no doubt wise, in most cases, to wait until the acute symptoms of localized peritonitis have subsided. Exceptions to this rule frequently occur, as when there are indications of acute suppuration and where the symptoms point to septic absorption.

DR. DOYEN of Paris read a paper on

(1) ABDOMINAL HYSTERECTOMY AND ITS INDICATION (TUMORS, SUPPURATION, ETC.); (2) MODIFICATION OF THE TECHNIC OF VAGINAL HYSTERECTOMY.

He said that abdominal and vaginal hysterectomy are not competing methods, but that each has its indication. He then explained the technic of the two methods and exhibited a clamp forceps, which he had devised, with which to crush the pedicle, thus preventing hemorrhage.

DR. JACOBS of Brussels read a paper, entitled

THE VAGINAL AND ABDOMINAL WAY.

After very careful study of several hundred cases the speaker had come to the conclusion that the danger is no greater in operating by one method than by the other. He had operated by the vaginal route 432 times, with 424 cures and 8 deaths; by the abdominal route 98 times, with 95 cures and 3 deaths.

DR. LANDAU of Berlin read a paper on

VAGINAL CELIOTOMY.

The author had operated in this way on 58 patients, opening multilocular cysts and the peritoneal cavity, and all had made uninterrupted recoveries. Those patients who have been operated on for non-inflammatory tumors have been cured permanently; in patients in whom inflammatory conditions led to operation, twenty per cent. were cured. Vaginal celiotomy is, after all, a laparotomy by a new route. The dangers are less than by abdominal section. He had seen only two cases in which the scar had yielded, one along its whole length, and the other only partially. From vaginal celiotomy must be excluded all tumors which must not be exposed to the liability to rupture, and he would also exclude all malignant tumors. All plastic operations on a normal sized uterus or adnexa can be done by way of the vagina. Vaginal celiotomy is considered by some as a good means of diagnosis, but he thought that if one knows how to palpate correctly this is not necessary. Vaginal celiotomy is a useful operation which in clearly defined cases furnishes good results, and on account of its relative freedom from danger should be preferred to other methods.

PROFESSOR SANGER of Leipzig said that during the last two or three years in Germany and France the general opinion had changed in favor of the abdominal method.

PROFESSOR FEHLING of Halle recommended puncture through the vagina for diagnostic purposes in difficult cases. He said that in suppurative pelvic peritonitis he made a large incision through the vagina. In chronic diseases of the adnexa, suppurative or non-suppurative, it cannot be determined which is the best method; surgeons are still experimenting. Drainage is important if the peritoneal cavity has been infected by pus, but if this has not occurred he closes it immediately. The abdominal route is attended by greater danger at the time and afterward, but if the operator is not quite sure, he should adopt the abdominal method, because he can see just what he is doing. When the uterus is sacrificed both ovaries should also be removed.

PROFESSOR MARTIN of Berlin said he was pleased to hear Dr. Cullingworth base his remarks on the clinical

features of the cases. If the disease is caused by gonorrhea the surgeon is bound to adopt a quiet and expectant method of treatment. He had been astonished to see a number of cases which were thought to be of gonorrheal infection at last prove to be instances of extra-uterine pregnancy. In some of these cases convalescence takes place; in others the patients suffer from extra-uterine deposits. Disease of the ovaries caused by the bacterium coli is more common than it is believed. Adhesions to the bowels, and invasion of the genital organs by the bacterium coli are frequently found. He recognized fully the indication for operating in poor patients who could not afford to spare the time to get well under good nursing. He would not remove the uterus if he could avoid it; patients who have retained their uterus are more benefited than those who have lost it. He advised that an organ which is amenable to further treatment should not be removed, for, if necessary, it may be removed later. He had not used drainage for many years. He adhered to the vaginal route, but confessed that there are limits to the adaptability of the method.

DR. MACAN of Dublin said that in this country it is the custom to put off operating as long as possible. He thought that operating simply because there is pelvic suppuration and a high temperature is not permissable. It is a personal equation entirely whether one incises the anterior or the posterior cul-de-sac or opens the abdomen.

PROFESSOR BYERS of Belfast said that the greater the surgeon's experience, the more accurate his diagnosis becomes, but there are cases in which the presence of pus, and the exact part involved, can only be settled by opening the abdomen. He thought that British operators had gone too far with the abdominal method. In his opinion when women have pus in the pelvis, and are in an exhausted condition, a vaginal incision will tide them over for a time until the abdomen can be opened. Operating during an attack of acute peritonitis is a very serious thing, and it is better to wait until the severity of the attack has subsided.

DR. HEYWOOD SMITH of London cited a case which illustrated the discussion: An Armenian woman came to him with an obscure fulness in the right side, high temperature, and pain. He decided to operate at once and found the right ovary and tube congested but free from disease, but from the center peeled a mass as large as an orange which contained the left ovary. The wound was closed without drainage and the patient is doing well. He thought that diseased ovaries lose their sensibility to pain, and that the pain in this instance was due to pressure on the healthy ovary. He entered a protest against the word "laparotomy" and thought "celiotomy" a better term.

DR. WARD COUSINS of Southsea advised waiting until absolutely well defined symptoms are present before operating in acute pelvic peritonitis, because many cases subside spontaneously, especially those due to gonorrhea. In the case of patients with irregular temperature and relapsing symptoms an operation is clearly indicated, and if there are changes in the tubes, the abdominal route is the best. He had never been compelled to operate in a case in which the symptoms were clearly due to gonorrhea.

DR. TAYLOR YOUNG of Sydney said that he thought that British surgeons labor under difficulties which German surgeons do not. The former meet with cases in a more advanced state than the latter, and consider conservatism more. He thought that a great mistake is made in England in not more universally adopting the dorsal position in examinations. After having made the diagnosis, the question of what to do is not so doubtful. If it is a simple abscess it should be treated in the same way as in any other part of the body; if it be multilocular and one-sided, incision should be tried first; if it is multilocular and bilateral, a radical operation is the only course to pursue. The adnexa and the uterus should be removed under these circumstances.

DR. A. LAPTHORN SMITH of Montreal thought it safer in acute peritonitis to wait until the attack has subsided. He felt that a definite rule could be laid down as to when to employ the vaginal route and when the abdominal. For large tumors located high in the pelvis, pus tubes, tubo-ovarian abscess, pyosalpinx, and tubal pregnancy the abdominal method is the best, but for small tumors, small ovarian cysts, small fibroids, and retroverted fixation the vaginal route should be chosen. He thought the uterus should be removed in cases in which the tubes and ovaries are removed. He said that the speculum designed by Dr. Doyen is of great advantage when operating in the Trendelenburg position. He has not drained for two or three years, and obtains better results than when he did drain.

DR. AMAND ROUTH of London said that almost all cases of parametritis are puerperal in origin, and are usually accompanied by indurations, rigors, and high temperature, and if the presence of pus is suspected, the peritoneal cavity should be opened. He aspirates, and if pus is found a couple of inches up the broad ligament he lays the sac open freely and drains thoroughly.

DR. MCCANN of London read a paper on

CLAMP AND LIGATURE IN VAGINAL HYSTERECTOMY FOR MALIGNANT DISEASE OF THE UTERUS.

He said that he had written his paper because there seemed to be two schools, one advocating the use of the clamp and another the ligature. He described the technic of his method of operating, and said that he leaves the clamp in position forty-eight hours. The great advantage of using the clamp is the larger amount of broad ligament which can be removed. He does not find convalescence delayed, or that sloughing occurs, and thinks that gauze plugs, left too long in the vagina, might account for some of the sloughing.

SECOND DAY—JULY 28TH.

The proceedings of the second day's session were opened by a discussion on

THE USE AND ABUSE OF THE MIDWIFERY FORCEPS,

which was opened by DR. MILNE MURRAY of Edinburgh. He stated that the selection of the subject for discussion arose out of the President's address delivered by Dr. Sin-

clair at Montreal last year, and quoted from the address as follows: "Midwifery has during the same period become also largely surgical—too surgical—and a thesis which I shall endeavor to maintain to-day is that gynecology has become so largely surgical as the direct result of surgical interference in midwifery practice. The accouchers are providers of material for the gynecologists. The term 'surgical' is employed here with almost exclusive reference to the midwifery forceps." Dr. Murray then asked, "What is the special value of the forceps as a surgical instrument?" It enables the physician to shorten suffering and to diminish the risk of childbirth; to diminish the danger to the mother and to greatly increase the safety of the child. The direct indication for the use of the forceps arises whenever the obstetrician is sure that the danger of interference has become less than that of leaving the patient alone, and in every case this is a matter of individual judgment, and there are many things to be taken into account, such as the state of the parturient canal, the efficiency of the pains, and the condition of the child. In every case the question arises: Is it safer to act or to wait? The obstetrician is not justified in interfering until he is sure waiting would be dangerous, nor is he justified in failing to act when it has been decided that there is danger in delaying.

Dr. Murray had come to the following conclusions: (*a*) The forceps is often used at the wrong time; (*b*) it is sometimes not used at the right time; (*c*) it is often badly used at both times. He summarized the dangers of the forceps, apart from the risk of septic infection, as follows: (1) The mother's parts may be bruised, lacerated, or otherwise injured by mechanical violence; (2) the too sudden emptying of the uterus may be followed by imperfect retraction, and there is danger in consequence of hemorrhage; (3) the fetal head may be unduly compressed, lacerated, or otherwise damaged.

The most striking illustration of the use of the forceps at the wrong time is their application through an undilated os, and particular attention was called to the spasmodically rigid os, which, during the interval between pains, is soft, flabby, and easily stretched, but which, during a pain, becomes tense, hard, and greatly narrowed. The speaker had seen cases in which the attendant, thinking the os fully dilated, had ruptured the membranes, and found after the uterine pains had begun again that the os was less than two-thirds dilated. The use of the forceps in a case like this is one of the gravest and too common examples of their abuse. On account of the tension and thinness, very slight efforts at traction will tear the cervix into the vaginal roof, inflicting dangerous injuries.

In speaking of the second point—not using the forceps at the right time—he thought it a mistake to wait four hours during the second stage, as has been the custom in the Rotunda Hospital, Dublin, but if, after the dilatation of the os, the advance of the head is blocked, either by the size of the head, the resistance of the canal, or the feebleness of the pains, he would not wait a moment before using the instrument. Nothing is to be gained and much is to be lost in waiting after progress is at an end, and the danger of interference is then less than the danger of waiting. The time element alone is not a proper basis for interference. In occipitoposterior positions of the vertex, when flexion is deficient, the sooner the forceps is used the better.

Lastly, the forceps is badly used when it is indicated and when it is not indicated. The first fault in technic is in not using the most efficient instrument. The advantages of the axis-traction forceps over the old forceps are very marked. In the axis-traction forceps one has not only a means of accomplishing delivery with safety and success, but he is able to avoid laceration of the pelvic floor in cases in which it would unavoidably occur if the further process of the labor were left to Nature.

The second fault in technic is in the application of the blades; they should be applied to the biparietal diameter of the head wherever it is situated. The speaker said that he was sure that extensive damage to the lower part of the vaginal canal had been done by oblique positions of the head and forceps at the outlet. Traction should not be jerky, but should begin imperceptibly, and should increase in intensity by even gradations, like a uterine pain.

Dr. Murray adopts the following method: The forceps, after being applied to the head, is held between the thumb and finger of the right hand, while the left hand is passed over the fundus of the uterus, enabling him to control the retraction, detect the beginning of a pain, and aid the action of the forceps by efficient pressure, acting as far as possible only with a pain, and taking care that the traction is effected in such a way as to maintain the advance of the suboccipitobregmatic diameter. In this lies the secret of success, for by means of this forceps one can restore and maintain the relation of the diameter to the outlet. There is one exception to the rule of extracting with a pain, *viz.*, in elderly primiparæ when, the head being low, every uterine pain is accompanied by a spasmodic action of the muscles of the vaginal floor which for the time narrows the vulvar orifice and throws the perineum into a state of tense rigidity. In these cases anesthesia should be deepened and traction avoided except during the intervals of the pains.

PROFESSOR PLAYFAIR of London spoke of the address of Dr. Sinclair at Montreal last year, and denied that obstetricians furnish material for the gynecologist. Even if these lesions are due to the abuse of the forceps it is no argument against its use. Every improvement in medicine is open to the same criticism; because the best treatments are humbugged is no reason why they should be left to the quacks. He spoke of the delivery and death of the Princess Charlotte, when the fetal head was on the brim of the pelvis on Monday, and she was allowed to drag along until 10 o'clock Wednesday night because the obstetricians in attendance would not put on the forceps. He said that Dr. Sinclair had never alluded to one of the greatest glories of modern times, that of the total abolition of craniotomy, due to the more frequent use of the forceps.

DR. SMYLIE of Dublin said that the axis-traction forceps is always used in Dublin. The most important points in the use of the forceps is to bear in mind the indications favorable for its use. The premature use of

forceps before the head has passed the brim may end in the obstetrician not being able to deliver the child, or in serious damage to the mother or child. The reason that patients are left for four hours in the second stage in the Rotunda Hospital is because the work is mostly done by students, and stringent rules had to be laid down for them.

Professor Fehling of Halle said that in Germany the teaching had to be very strict on account of the dreams of the students that every woman should be delivered by forceps. He thought very highly of the axis-traction forceps, but thought it more dangerous in the hands of the beginner than in those of a skilled operator. Three conditions are necessary before the forceps is allowed to be used: three-fourths of the head must have passed the brim of the pelvis, the os uteri must be dilated, and there must be good rotation of the head. Out of 3000 cases in the out-patient clinics forceps has only been employed 294 times, and not a single mother has been lost from the confinement itself, and only six children.

Sir William Priestly said that good should come from warning the younger practitioners to be careful how they use the forceps, the kind to use, and when to use it. More children are saved and less damage done than when he began to teach, nearly fifty years ago. In former days much damage was done by delay. He had seen damage done, not only to the roof of the vagina but also to the cervix uteri from the premature use of forceps.

Professor Stephenson of Aberdeen said it was a country practitioner who first demonstrated the value of forceps. He does not follow the rule of using forceps when the symptoms indicate danger to the mother or child, but tries to prevent these symptoms. His motto is, "Help Nature, and render the parturient force more efficient, or supplement it when deficient." In referring to the question of rotation and flexion, he said that to produce rotation is to produce flexion. A delicate touch and a full knowledge of the mechanism of labor are the essential factors.

Professor Sinclair said that there was a misunderstanding as to his address of last year, and that he had said nothing to suggest that he favored going back to the old practice of midwifery. He said that in Lancashire there are more cases of vesicovaginal fistula now than in the old times. He had seen more cases of damage from the premature use of forceps in the last ten years than he saw during the first ten years of the old practice. It is not the accoucheur who sees the injury done by his forceps, but the gynecologist, especially in the out-patient department of the hospitals, and the opinion that he has formed after twenty years of this experience is the result of clear conviction. He did not intend to teach the whole world midwifery, but he thought it time to take stock of our position and to consider whether we are not abusing these instruments. He thought the teaching of midwifery in the English schools as bad as it could well be. Until men are able to diagnose with exactness, and have some knowledge and judgment behind the delicate touch which has been spoken of, they will not do much good; many put on the forceps, pull the head out, and diagnose the position afterward.

Dr. Jardine of Glasgow said that ten per cent. of the cases in the Glasgow Maternity Hospital last year were of contracted pelves, and delivery by forceps was safer for both mother and child. With a true conjugate of three inches he had delivered a living child weighing 8½ pounds. The axis-traction forceps is the only instrument to use. As to applying the forceps with reference to the diameters of the head, it is theoretically correct but practically impossible.

Dr. More Madden of Dublin then read a paper on

Some Improvements in the Mechanism and Use of the Midwifery Forceps, and in its Employment.

He said that the timely judicious use of the forceps is the greatest triumph of our art. The majority of cases in which it is used are those in which there is delay in the second stage; delay in the first stage is not of so much importance. The two most common causes of this delay are uterine inertia and some mechanical obstruction arising from some disproportion between the fetal head and the maternal passages; in both of these the forceps is valuable. There should be a due proportion between the force employed and the resistance to be overcome. He showed an instrument of his own devising which had great compressing power, and was only intended for those cases in which embryotomy would otherwise be employed. He also showed a pair of forceps, very simple in construction, which were designed to come in contact only with the fetal head, and a pair of tractors which could be fitted to any forceps. He did not think the vagina should be washed out before using forceps, but should be immediately after. He had never resorted to craniotomy or Cæsarean section, although he had been connected with a maternity hospital for thirty years.

Dr. Mary Scharlieb of London read a paper, entitled

A Case of Missed Labor Verified by Operation and also Post-Mortem.

The case was one in which a fully developed fetus was retained beyond the limits of normal pregnancy, died in utero, and was retained until delivered by artificial means.

Dr. Robert Jardine of Glasgow read a paper on

Aseptic Midwifery.

He said that while puerperal fever has disappeared from the maternity hospitals, in private practice it has slightly increased during the last forty years. He spoke of the great importance of adopting strict septic precautions. Lysol, he thought, is the best all-round antiseptic, because it does away with greasy lubricants, which are more or less septic. Special attention should be paid to the external genitals, and examinations should be conducted with the buttocks and vulva in plain view in order that the hands may be kept from touching anything after being sterilized.

(To be continued.)

REVIEWS.

DIE PATHOLOGIE UND THERAPIE DER STERILITAT BEIM MANNE. Von DR. E. FINGER, a. o. Professor an der Universitat, Wien. Leipzig: Arthur Georgi, 1898.

THIS is the first half of a work on sterility, the second portion of which is to be written by Professor Saenger. The well-known studies of Professor Finger in the diseases of the male genital organs have furnished a substantial basis for the present volume.

After discussing the physiology of erection, he enters upon a consideration of the cases of impotence which rest upon anatomic changes. This is followed by a chapter on the causes of impotence which depend upon a functional basis. The symptomatology, pathology, and treatment are next described, the author laying especial stress on the psychic treatment of these cases. He insists, however, upon a sharp distinction between organic and functional disorders of the sexual organs, and would have, in appropriate cases, appropriate treatment directed toward those conditions which are responsible for organic disturbances of the male organs.

The second portion of this work deals with the consideration of those cases in which intercourse is possible, but in which insemination or impregnation are impossible. The author divides these cases into two classes: those in which the sterility arises through pathologic changes, and those in which it is caused by a disturbance in the inseminating apparatus.

The appendix containing the literature of the subject adds value to the work. To those interested in this branch of medicine, as well as those who have to do with cases of this nature in practice, the work can be most heartily recommended as a scientific exposition of the subject.

TRANSACTIONS OF THE NINETEENTH ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION, held in the city of Washington, D. C., May 4, 5, and 6, 1897. New York: D. Appleton & Company, 1898.

THE interesting papers collected in this volume, as well as the notes of the discussions following their reading at the meeting are ample proof, were any needed, that with the marvelous growth of specialism in medicine, laryngology has more than held its own. The topics treated are, almost without exception, taken from the domain of clinical diagnosis or operative surgery. Experimental pathology is represented in but one treatise, one of the best in the volume, by Drs. Park and Wright, on "Nasal Bacteria in Health." The Association has cause to flatter itself on the high character of its work.

THE BULLETIN OF THE OHIO HOSPITAL FOR EPILEPTICS. January, 1898. Published by the Hospital.

THE Bulletin contains several valuable pathologic articles by Dr. A. P. Ohlmacher, director of the pathologic laboratory. It opens with a detailed report of the clinical and pathological features of six cases which came to autopsy. The anatomical findings are given in detail, and four of the six cases gave evidence of the lymphoid constitution upon which so much stress is at present being laid by pathologists. It furnishes, as well, the topic for Dr. Ohlmacher's second article in which he looks upon these findings as a possible pathological basis for some forms of epilepsy. Several beautiful photographic plates enhance the value of the bulletin.

THERAPEUTIC HINTS.

Gastric Hyperacidity.—

℞ Sodii sulphatis	. . . .	℥ i
Potasii sulphatis	. . .	gr. lxxx
Sodii chloridi	. . . .	℥ i
Sodii carbonatis	. . .	ʒ vi
Sodii boratis	. . . .	ʒ iiss.

M. Sig. Half a teaspoonful in half a glass of warm water before breakfast and two hours before the two other meals.—*Wolff.*

Boaz has found the action of the above very efficacious in diminishing the secretion of hydrochloric acid during digestion as well as when the stomach is empty of food. He recommends also the following powder:

℞ Magnesiæ	. . .	℥ ss
Bismuthi carbonatis, Sodii carbonatis	aa .	gr. lxxx
Ext. belladonnæ, Ext. nucis vomicæ	aa .	gr. iss–gr. iii.

M. Sig. Half a teaspoonful three times a day half an hour after eating.

Mixture for Intra-Urethral Injection in Gonorrhea.—Pousson reports favorable results from the use of the following, the formula being based on the principle that a mixture of several antiseptics exhibits more energetic therapeutic action than any single one of the same even in strong solution:

℞ Menthol	. . . . .	gr. ½
Acidi salicylici	. . . .	gr. iss
Acidi carbolici, Acidi lactici, Ol. eucalypti, Methyl salicylatis	aa . .	gr. iii
Resorcin	. . . . .	gr. viii

ORIGINAL ARTICLES.

THE EDUCATION OF THE SENSE OF SMELL.

BY A. L. BENEDICT, M.D.,
OF BUFFALO, N. Y.;
PROFESSOR OF PHYSIOLOGY AND DIGESTIVE DISEASES IN THE DENTAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

MY attention was first called to this subject during a lecture on the special senses. Alluding to the power of distinguishing individuals by the sense of smell, and asking how many of the class possessed this power, I was surprised to find that not one out of fifty or sixty replied in the affirmative, nor has my experience with subsequent classes been different. The rarity with which human beings make any effort to cultivate this faculty, and the difficulty of securing data, will be an excuse for drawing largely on personal experiences. In order that such experiences may appear fairly as individual observations, not as general traits, this article will necessarily assume, in places, an appearance of egoism.

As pointed out in conversation by Professor Woods Hutchinson, the present method of training children is such as to repress the intellectual use of the sense of smell. To smell of food subjects the child to dismissal from the table; to ask, "What smells?" is considered vulgar; to say, "Who smells?" is treated as an indecency. In fact, in our endeavor to be "nice," we even confuse the verb *smell* with the always intransitive verbs, *reek* and *stink*, as is well illustrated by an anecdote of the lexicographer Johnson. A lady, in remonstrating with him for his well-known carelessness in matters of the toilet, said, "Positively, doctor, you smell." "You are wrong, madame," replied the doctor, "you smell, but I stink." In view of the prejudices alluded to, I must ask my readers to follow the subject in a scientific spirit and especially to guard against the tendency to associate animal odors with the ideas of uncleanliness or indecency.

Man has been so much in the habit of regarding himself as the culmination of the animal kingdom that it is well for him to receive some humiliation in studying comparative anatomy and physiology. While he certainly has the largest and best developed central nervous system, his digestive apparatus is far inferior to that of the herbivora, and his special sense organs are surpassed in one or more particulars by almost every one of the higher mammals. The bulb of the olfactory nerve is almost a cerebral lobe in some animals. We are in the habit of classifying sight and hearing as intellectual senses and applying some contrasting term to the other seven (touch, pressure, muscular, temperature, equilibrium, taste, smell). The most superficial study of language, which is a convenient gage of mental development, shows that the vocabulary connected with the sense of smell is more limited than that for any other sense, and that for smell alone we are entirely lacking in general descriptive terms, though tastes, also, must be spoken of by comparison with known perceptions. With dogs, and some other animals, such a low ranking of the sense of smell is very far from being the case. Just as we feel only half acquainted with an object which we have touched but have not seen, so a dog is evidently not fully satisfied with sensations arising from the eye and the ear; he must supplement them with those of smell before he has fully framed his concept. Not only does he recognize human beings by the sense of smell, but all the social amenities of dog life, all his hunting instincts, all his conscientious guardianship of domestic animals, and much of his mischievous sport, are connected with smell. Probably few persons have failed to notice that urination with dogs is more than a physiologic act. In cities, especially, smelling and urination occupy a great deal of the dog's attention and there is certainly as much intelligence called into play as in the hide-and-seek games of children. Indeed, after setting aside the first sentiment of disgust, one can recognize a very elaborate etiquette in the use by the dog of his olfactory sense. Not to pursue this branch of the subject further, let us study the sense of smell in the human being with the admission that we have persistently neglected this sense for generations until we have become, in this regard, idiots by deprivation. Let us also endeavor to educate the remains of this sense as we would the imperfect power of hearing, sight, or touch in a defective patient.

The odor of the healthy, clean human being arises from the perspiration and the sebaceous secretion. Neither of these contains as an important chemic ingredient a volatile substance, and whether the volatile excreta from the skin are more properly considered as perspiratory or sebaceous in origin, I shall not pretend to say. There are minor differences in the physiologic chemistry of different individuals which are manifested by varied appetites, varied

power of growth, varied power of assimilation, conspicuously of fats but quite as genuinely of other foods, and, not to mention other idiosyncrasies, by peculiarities of the effluvia of the skin. Some human beings who have the power of distinguishing individuals by odor have described the odor as usually agreeable and, often, in the case of persons of the opposite sex, as an excitant of passion. This is certainly true of dogs. Personally, the odor of a human being is neither agreeable nor disagreeable to me, and is entirely free from sexual or other sentimental suggestion. It is simply a discrimination, unqualified by any associated idea. Of course, this statement refers to clean persons—those whom most others would consider practically odorless—and I may say that the cultivation of the sense of smell has not—as use or study is said to do in general—diminished in the least the esthetic ideas usually connected with odors. In fact, I am almost painfully affected by many food-odors, such as onion, cabbage, turnip, etc., and by certain perfumes, such as musk, the scent of hyacinths, easter-lilies, tube-roses, etc. None of these aversions of smell, however, are insuperable or sufficient to interfere with the gratification of hunger or the discharge of any duty.

The unclean human body affords odors which may be of diagnostic importance, or, at least, may aid in that detective work which every physician has to perform in estimating social standing, habits, and other circumstances in connection with the practical care of the sick. The following odors may be detected, singly or combined: (1) Neglected skin secretion, sebaceous or perspiratory. (2) The special odor of the axillæ. (3) The special odor of the smegma. (4) The special odor of the perineum. 1, 2, 3, and 4 refer to general or modified secretions from sebaceous glands, with the accidental admixture of truly sudoriferous odors. (5) Urine. (6) Feces. (7) The special odor of the scalp, which, perhaps, should be included with the first four. (8) Breath. (9) Menstrual blood or other secretion. (10) The odor of the feet, which is not a sebaceous odor but due to the decomposition of macerated epithelium. (11) Extrinsic odors permeating clothing, hair, etc. (12) Certain vegetable or drug-odors which escape through many routes, but especially through the skin. (13) Perfumes, as in soaps and other cosmetics.

The terms clean and unclean are relative and by no means dependent on refinement, social position, etc. It is absolutely impossible for any one to keep immaculately—or rather inodorously—clean and have time for anything else. Owing to personal differences in chemistry, some may remain free from noticeable odor while careless as to bathing, and, on the other hand, the greatest pains in bathing and changing underwear may not be sufficient to offset a tendency to bromhydrosis. I once attended an old woman who had chronic Bright's disease in the mild, interstitial form. The recommendation of hot bathing to stimulate the skin elicited the fact that the patient had not had a bath for about forty years, yet she was not marked by a disagreeable odor. Persons illustrating the opposite extreme deserve our sympathy and forbearance, rather than the ridicule which is so freely bestowed. Women require more frequent attention to the toilet than do men, even when not menstruating, and when such factors as constipation and lack of exercise do not exist. While perspiration causes a noticeable odor, persons engaged in active exercise who sweat much and bathe sufficiently are much less odorous than those who take little exercise and, hence, retain products of imperfect metabolism in the system. Very fat persons and those with acne, comedones, and wens, are liable to the development of valerianic acid and more or less closely allied bodies. It is largely this substance that gives the peculiar sour odor to accumulations in the umbilicus, beneath the breasts, or other folds of the skin. It is sometimes possible to squeeze from a small wen a thread of sebaceous material may feet or even yards long, having a marked odor of valerianic acid. While fat women are very apt to be disagreeably odorous, the axillary odor is usually marked in lean brunettes. Just why the axillary odor should be so much more marked in women than in men is difficult to explain, unless on account of the warmth of the corset and the wearing of tighter garments. Many women are nuisances simply because they neglect to use sleeve-protectors or to keep clean those that they do use. Often the absence of a bath-tub or the necessity of dressing in a cold room is a crucial factor.

The odor of smegma, urine, feces, and feet usually indicates a rank infringement of the laws of decency. The first may indicate a stimulation of sexual passion and may, therefore, be of value in recognizing cases of hysteria. Quite recently this was the case in regard to a patient whom I was summoned in haste to see some time after having treated her for subacid dyspepsia. The young man in the case was admonished as to his future conduct. It is questionable whether the sexual excitement was merely the cause of the hysteric seizure, or of the dyspepsia, also. In the *Journal of the American Medical Association* of February 19, 1898, Dr. Charles Provost Grayson calls attention to the sexual factor in the production of nasal hyperemia and inflammation, and alludes to the existence of other reflex manifestations of the same emotional cause. Physicians must realize the

importance of this subject and consider it without false modesty. The smell of urine may indicate stillicidium in women, prostatic disease in men, enuresis in children, and various other causes of impairment of the sphincter and urethral muscles. It is easy to distinguish the odor of decomposed normal urine from the reek of that which has undergone alkaline putrefaction in the bladder, along with the decomposition of mucin (or nucleo-albumin?). As is well-known, the urine may be odorous from the ingestion of asparagus, turpentine, and various other foods and drugs. A fecal odor may indicate the presence of a fistula or some interference with the tone of the sphincters. By the odor we may distinguish between fat decomposition, with the production of fatty acids, the putrefaction of proteids, including blood, and the sourness of carbohydrate fermentation. After the evacuation of fecal contents by a diarrhea, a characteristic saline (?) and not especially disagreeable odor may indicate the loss of serum or of mucus. Sometimes, even the odor of orange, lemon, etc., may be distinguished, as well as that of certain drugs. In one case about which I was consulted, the appearance of the little sacs in which the pulp of orange is contained had occasioned considerable alarm and, while the low power of the microscope was the crucial test, the mere odor of the fecal fluid was significant. Foods like beans and eggs, which are rich in sulphur, usually produce H_2S and CS_2. The latter gas seems to be more slowly volatile than most other odorous intestinal gases; at any rate it is more persistent and gives the idea of staleness in regard to a discharge either of feces or of flatus.

The odors of the feet and of the scalp have no special diagnostic value in my experience, although they should have to a dermatologist. In justice to patients, it must be remembered that blacking, paste, and badly tanned leather may be responsible for an offensive odor; also, that excessive sweating of the feet is a disease, not a filthy habit. The odor of the breath may be due to nasal, pharyngeal, or even frontal or other sinus disease, to ulceration of the gums, cheeks, etc.; to decomposition in and about the teeth; to decomposition in tonsillar crypts; to laryngeal, pulmonary, or gastric disease. The fetid odor of ozena is classic, but in mild affections there may be retention and decomposition of mucus, epithelium, and débris. From hospital experience I can say that phthisical patients are apt to develop a peculiar sour odor of the breath, especially after cavities have formed. The odor of mercurial stomatitis has been described as characteristic, but, personally, I have not been able to distinguish it from that of noma or of any other extensive ulceration or necrosis of comparable extent and degree. Foul breath may be due to the lodgment of food between sound teeth, and cleaning of the teeth should not be considered thorough unless the brush is preceded by the use of floss or, better yet, of loosely twisted shoe-thread.

The back of the tongue is a fertile breeding place for bacteria and molds, and is often in league with similar but perhaps less marked processes in decayed teeth, tonsillar crypts, etc. The wonderful "sympathy" between gastric conditions and those of the tongue, which aroused so much attention ten years ago and more, is similarly explained. Sour eructations do not usually produce more than a temporary odor of the breath, but, in any marked stomach trouble in which bacterial action is unrestrained, the same process is apt to take place in the trough of the tongue. Hepatic and intestinal lesions produce bad breath, apparently from the absorption of toxic substances, not odorous in themselves but capable of reducing the resisting power of the mouth to bacterial action. Gangrene of the lungs has a quite characteristic odor. In diabetes, not only the breath but all secretions may be perfumed with what was formerly supposed to be acetone. The worst breath is due to the filthy practice of stuffing dental cavities with cotton. A woman addicted to this practice is mentioned by her acquaintances as "The pestilence that walketh by noonday." Alcoholic beverages are well known to impart a characteristic odor to the breath, and thus to give a warning to the diagnostician. But we must not confuse the odor of bay rum used as a cosmetic nor forget that the man with whisky on his breath may have an apoplexy or that he may have taken a single drink, innocently, because of the commencement of symptoms that have subsequently overcome him. The odor of chronic alcoholism is quite different from that of recent imbibing.

The odor of menstruation is occasionally diagnostic but it is mentioned here rather for the sake of emphasizing that it may be utterly unpreventable, persisting in spite of the most careful toilet possible. Whether curettement would be indicated for this symptom, is a question for the gynecologist. The odor of the clothing often throws light on the habits, occupation, and social status of a patient. Some teacher has written eloquently of the "Smell of dirty little boys on a wet day." Men who work about horses have a characteristic, and, to many persons, not disagreeable odor. Occupation about other animals is often detectable by the odor. The combined bovine and lactic-acid odor of the milkman is conspicuous. Good and bad leather and many other commodities are odorous. I must confess that I

cannot always distinguish a lady from a "loidy" by the dress and must often rely on the odor of perfume. The quality of tobacco, its use for smoking or chewing, the amount used, are quite distinguishable by the smell, and are of considerable indirect value. The clothing of even the cleanly poor, who have not the privilege of bath-tubs and who must hang their garments where they are penetrated by the fumes of cooking, often assumes a vile odor. New garments, recently moistened and pressed, are often quite offensive. Persons who eat garlic, onions, etc., must expect to have strong-smelling secretions, which no amount of external cleanliness will offset.

Juvenal, centuries ago, addressed an epigram to a perfumed fop as follows: "You smell well, therefore, I think you smell ill." The character of perfume is a very fair index of social status. Musk we naturally associate with bleached hair and a stained character. Musk plus iodoform, in the absence of a visible lesion, is a not uncommon combination and suggests not only bad morals but venereal infection. Bergamot and other abominations of the barber-shop often stamp that class of men for whom we have no more reputable term than "mucker."

In very few instances is there a characteristic odor directly diagnostic of disease. The mousy smell of favus and the odor of variola are classic. Some physicians speak of a characteristic odor of typhoid. This is a mistake; the odor is due partly to sour milk from the diet and partly to the intestinal intoxication and may be encountered in any low fever. The so-called acetone odor of diabetes has already been alluded to. Some idea of the amount of waste carried off by the kidneys may be obtained by the pungent odor given off when the urine is boiled. Such volatile excreta are certainly highly toxic but their exact nature is not understood. Urine loaded with indican and other products of intestinal putrefaction is apt to develop a foul odor quite distinct from that of normal but condensed urine. The interval between the ingestion of asparagus and the appearance of the odor of methyl mercaptan in the urine may be used as a rough test of absorption. Normally, the odor should be marked in four hours and should continue for about eight hours longer.

In examining the gastric contents we make practical use of the nose to distinguish acetic and butyric acids, and we may also distinguish the mixed sourness of carbohydrate fermentation—which must not be confused with that of fruit ingested—the putrefaction of albumin in serious ischochymia, and the carrion-like smell of cancer. Personally, I would place as much stress on the last as on any other single sign of carcinoma except tumor. The presence of H_2S in the stomach contents or eructated gas is almost positive evidence of regurgitation of the bacillus coli communis from the large, and the lower part of the small, intestine, unless foods rich in sulphur have been eaten.

A short time ago I was called in consultation to see an infant who had had an obstinate diarrhea for some days, not relieved by treatment. Physical examination revealed practically nothing, but, during it a quantity of foul intestinal gas was discharged on which I felt warranted in basing the diagnosis of proteid decomposition which usually follows marked failure of the secretion of hydrochloric acid. Treatment accordingly, with hydrochloric acid and eudoxin, a bismuth salt containing iodin, relieved the the trouble in thirty-six hours. In a few cases of gall-stones and of hepatic sclerosis I have detected peculiar odors not encountered elsewhere, and which I believe to have some diagnostic value. Of course, they are quite indescribable.

Problems of toxicology are often solved by the sense of smell. The general anesthetics, hydrocyanic acid, alcohol, carbolic acid, some opiates, cannabis indica, camphor, and illuminating-gas may be mentioned. There is now awaiting execution a man convicted of murder mainly on the testimony of a physician who gave a death-certificate as due to natural causes, whose suspicions were later aroused and who then made a positive diagnosis of hydrocyanic-acid poisoning, from the odor of the brain several days after death and after embalming was claimed to have been done. As the brain has normally a peculiar odor, which may described perhaps as spicy, and as the physician did not have frequent opportunity to make autopsies, one may be pardoned for questioning whether the odor of hydrocyanic acid was really present. The presence or absence of formol in embalming fluids is often important in diagnosing between the peculiar hard state of bowel thus embalmed while in rigor mortis and pathologic conditions.

In sanitary practice one of the best tests for leaks in sewer or other pipes is that by volatile and odorous substances, such as peppermint. Or, we may substitute the oil of catnip and use the more acute olfactories of a cat. Similarly, I have used the peppermint test in diagnosing against intestinal occlusion.

This paper is intended to call attention to the possibilities of using the nose as a practical aid to the physician, not as a complete treatise on the subject. Many interesting observations on this topic may be found in Gould and Pyles' "Anomalies and Curiosities of Medicine." Criticisms and reports of the observations of others will be most gladly received.

AMPUTATION AT THE SHOULDER-JOINT; A SERIES OF EIGHT CASES WITHOUT A DEATH.

By MANNING SIMONS, M.D.,
OF CHARLESTON, S. C.

Amputation performed by modern methods has given greatly improved results so far as the mortality of these operations is concerned. A review of the statistics is especially interesting as showing the improvement to be noted in relation to amputations performed at the shoulder-joint. Much of the improvement in mortality-results may be attributed to what is now familiarly known as "aseptic surgery." Indeed, the success of amputations for injury depends more upon the first treatment of the wound than upon the skill of the operating surgeon. For the same reason the great mortality formerly attendant upon compound fractures has diminished in proportion as this fact is understood and appreciated by the rank and file of physicians under whose observation and attendance these cases come before they reach the surgeon. Again, the modern bloodless methods with which the names of Esmarch and Wyeth are inseparably connected have done much to reduce the mortality associated with amputations.

A writer, in a system of surgery published not more than ten years ago, says: "Amputation at the shoulder-joint is in appearance a most formidable operation, yet its results are upon the whole successful." The mortality-table presented by this authority gives a death-rate per cent. in this operation varying from 33.3 to 76.9. He compares these figures with those of amputations in different parts of the body, and remarks that it is seen that the death-rate of shoulder-joint amputations, which is less than two in five, is not much greater than that of amputation of the leg, and very much less than that of amputation of the thigh.

Since this operation was actually put into practice in the early part of the last century it has been performed in a variety of ways. Sedillot enumerates at least twenty, Velpeau thirty, and Lisfranc thirty-six. This variety of methods indicates that the operation, in the light of modern surgery comparatively simple of execution, taxed the ingenuity of surgeons in its perfection and development. Most modern authorities seem to have eliminated all of these methods except three, each with one or more modifications. The following seem to have maintained their hold upon the favor of surgeons: The oval or racquet method of Larrey; the external flap method by transfixion known by the name of Dupuytren; and the anteroposterior flap method of Lisfranc. Until Wyeth brought to notice and to practical application his bloodless method, the only safeguards against hemorrhage were compression of the subclavian artery upon the first rib, either by a finger, or by means of an object such as a wrapped key. The real mainstay, however, was the skilful assistant who followed the knife of the surgeon as he severed the brachial artery with the final sweep. Even under the most favorable circumstances a large amount of blood was lost in the severed limb. With Esmarch's bandage, and with Wyeth's method properly carried out in faithful detail, the loss of blood beyond oozing from divided capillaries in the extensive wound surface and from small muscular branches after removal of the rubber tubing is trifling in amount.

In applying this method experience derived from these cases induces me to call especial attention to one precaution. "It is essential that both pins emerge one inch internal to the top of the acromion; otherwise, when the humerus is disarticulated, the tubing tends to slip down, thus drawing the flaps together when the vessels may retreat, severe hemorrhage then occurring, necessitating ligature of the subclavian artery or removal of the tube to secure the vessels in the wound, the latter only being possible of execution after severe loss of blood." The chief vessels, *viz.*, the brachial, subscapular, and posterior circumflex, should be secured before the tubing is removed, and usually they are easily seen and taken up.

The case reported first in this paper was an object lesson to me in ligatures, exemplified by the occurrence of secondary hemorrhage from the brachial artery on the fifth day. Doubtless the most fruitful cause of this form of hemorrhage is septic inflammation which prevents the process of healing in the vessels or destroys that which may have occurred. In this case too early softening of the non-chromicized catgut ligature was the cause of the hemorrhage. The wound, which had healed along the line of incision, was with some difficulty opened up and the bleeding vessel found freed from the ligatures by absorption and softening of the latter. According to my usual custom, chromicized catgut is used to ligate vessels in amputation, but on this occasion there was none at hand and non-chromicized gut was used, with the result mentioned.

In one of these cases the amputation was done by Larrey's or the oval method, the others by intero-external flaps by dissection from without inward. The operation is not difficult of performance, but the chief trouble experienced is in the division of the muscles surrounding the joint, subscapular, supra- and infraspinatus and long head of the biceps. In Larrey's operation these muscles are reached through a vertical incision and such space as may

be obtained by the separation of the tissues on each side from the bone. At best the cutting of the insertions of the muscles must be done by touch rather than by sight. Dupuytren's operation by transfixion, after raising of the flap, gives a good view of the muscular attachments to be severed, but it has the disadvantage that there is difficulty in carrying the knife sufficiently far around the prominence of the head of the humerus to get a wide-based, well-rounded external flap, which necessarily contains all of the deltoid. The method by dissection from without inward, I believe, obviates these difficulties and objections and greatly simplifies the operation.

This operation seems to have attracted but little attention and is either not mentioned at all or is simply alluded to in recent text-books and systems of surgery. In the "International Encyclopedia of Surgery" it is dismissed as follows in the description of Dupuytren's operation by transfixion: "A modification, and I think an improvement of this method originally practised by Cline, and first described in this country by Dr. J. A. Smith of New York in a letter to Dorsey, consists in cutting a deltoid flap of curved outline from without inward, then disarticulating and finally completing the operation in the way already described." In the "System of Surgery" by Dennis, under the head of the modified oval operation, is described a method in which an external flap is made by cutting from without inward, but it lacks in simplicity as compared with the operation performed in several of the cases here reported.

The operation I have found simple and of rapid execution is described by Druitt as a method that "may be employed." In operating by dissection the surgeon may stand facing the patient and take hold of the arm, leaving the external flap to be raised by an assistant, or he may stand outside either limb and take hold of the flap himself. The latter plan, I think, is the more convenient, and in all my operations by this method I have managed the flap myself and entrusted the arm to an assistant. The arm being carried inward and forward by an assistant, the surgeon commences his incision just outside of the coracoid process, carries it down to the insertion of the deltoid, and then making a well-rounded turn ascends to a point above the angle of the posterior axillary fold just below the spine of the scapula near its root. The skin is everted below and the flap, consisting at first only of skin and subcutaneous tissue, is dissected up, but taking more and more of the deltoid until at its base it includes the whole thickness of that muscle. When this flap is raised the capsule of the joint is fully exposed and the muscles to be divided are easily in reach, and plainly to be seen. The arm being now strongly adducted, the capsule is opened by a strong cut upon the head of the bone, the knife is passed between the scapula and humerus and down along the inner side of the latter for a sufficient distance, then directly inward. If the pins and tubing have been properly placed, the assistant need not compress the artery as formerly advised.

The wound is swabbed with chlorid of zinc. A drainage-tube having been introduced the wound is closed with silkworm gut, the line of apposition of the flaps extending from above downward and outward. The wound dressings are, first, sterilized gauze next to the wound, then iodoform gauze, then bichlorid gauze, cotton, and a snug bandage. The drainage-tube is removed in forty-eight hours. In my series of cases healing occurred without suppuration, except in one instance in which the operation was performed for a sloughing sarcoma of large size in the neighborhood of the elbow-joint. According to the notes of this case, the suppuration occurred at one point and ceased at the end of four days.

CASE I.—T. N., a Syrian, was admitted to the City Hospital, December 18, 1895, suffering from a burn which had charred his arm nearly to the shoulder-joint. Amputation performed at shoulder-joint. Secondary hemorrhage on 5th day. Discharged cured January 11, 1896.

CASE II.—S. G., black, male, aged twenty-nine years, was admitted to the City Hospital, December 28, 1896, suffering from a gunshot wound of the right arm. The weapon used was a double-barreled shotgun loaded with No. 4 shot. Next day the arm was taken off at the shoulder-joint. The outer flap was perforated by twelve of the shot. The patient made an uneventful recovery. Discharged February 5, 1897.

CASE III.—John S., black, male, aged fourteen years, was admitted to the City Hospital, December 30, 1896, suffering from a crushed arm, caused by a railroad accident. The arm was amputated the same day. Patient made an uneventful recovery and was discharged February 1, 1897.

CASE IV.—Joe W., black, male, aged sixteen years, was admitted to the City Hospital, October 3, 1896, suffering from a compound fracture of the humerus. Amputation at shoulder-joint. The patient made an uneventful recovery and was discharged October 22, 1896.

CASE V.—Jacob B., black, male, aged fifty years, was admitted to the City Hospital, January 18, 1897, suffering from a malignant tumor of the right arm just below the elbow. It was gangrenous. Amputated January 19, 1897, at the shoulder-joint. Wound suppurated for four days. Patient made a good recovery and was discharged cured March 1, 1897.

CASE VI.—Ishmael G., black, male, aged four-

teen years, was admitted to the City Hospital, March 16, 1897, suffering from a gunshot wound of the right arm. The weapon was an old musket, loaded with No. 5 shot. The arm was nearly cut from the body. It was amputated the same day at the shoulder-joint. Patient made an uneventful recovery and was discharged April 7, 1897.

Case VII.—William J., black, male, aged twenty years, was admitted to the City Hospital suffering from a compound fracture of the right arm. Amputation was performed at the shoulder-joint. Patient made an uneventful recovery.

Case VIII.—Jennings H., colored, male, aged twenty-eight years, a large, well-muscled phosphate hand, entered St. Francis Xavier's Infirmary, January 20, 1897, at 9 P.M. During the afternoon, while riding on a car, he slipped and fell in such a manner that the wheel of a loaded freight car passed over the arm below the shoulder-joint. The arm was almost completely severed and the bone crushed so as to render maniputation impossible except with the aid of the lion forceps. Hemorrhage had been profuse but was checked by some of the bystanders who tied a piece of twine tightly around the arm. Amputation was performed at the shoulder-joint about 10 P.M. of the same day. Subsequent to the operation his temperature never rose after the second day, and on the third day the tube was taken out. The wound healed by first intention. Every second stitch was taken out on the ninth day and the remaining ones on the fourteenth day. He was discharged cured on the twenty-first day.

CHRONIC ARTICULAR RHEUMATISM AND LUMBAGO TREATED BY COLD OVER THE SPINE.

By BEVERLEY OLIVER KINNEAR, M.D.,
of New York.

In chronic articular rheumatism the regulation of the circulation of the blood throughout the body by means of cold applied over the spinal nerve-centers will, without the aid of internal medication, restore the patient to health or ameliorate his condition.

The reason that cold over the spine will accomplish this result is because when properly and intelligently applied it will always dilate the arterioles and capillaries throughout the whole organism and increase the external heat of the body very perceptibly. This signifies more rapid metabolic changes, increased general nutrition, and restoration to normal function in the tissues. That cold over the spine restores diseased tissues to health is practically proved by the results of the applications; the patients steadily gain in strength, in appetite, and in digestion, and soon begin to manifest an increased energy of mind and body. The ice-bags which are to be used should never be wider than four and a half inches for the adult, otherwise the body will be chilled. The length of the bag depends on the age and size of the patient.

The fact now generally recognized that metabolic changes or processes are largely under the control of the nervous system, throws a new light upon rheumatism, as it does also upon all inflammatory disorders. That the cerebrospinal nerves when excited, after severance by electricity applied to the terminal section of the nerve, will give rise to heat and swelling in muscular and connective tissue was proven by Brown-Séquard when he stimulated the cut end of the chorda tympani nerve, and noted that not only did the submaxillary gland discharge very freely, but that the tongue became hot, red, and swollen, indicating thereby that stimulus of the cerebrospinal nerve caused active hyperemia with effusion in this muscle and its connective tissue and mucous membrane. It is also quite widely believed to-day that every motor nerve carries with it a trophic or vasodilator fiber, and if this be true of the nerve-supply of all the tissues in the body, it is very easy to realize that excitement of cerebrospinal central cells, will, if sufficiently strong, give rise to inflammations in the distal areas controlled by the centers.

This view is enforced from the clinical standpoint by the application of cold over the spine in many forms of chronic inflammation. By the intelligent use of such applications it is possible rapidly to subdue inflammatory forms of skin disease, chronic forms of inflammation in the mucous membranes, such as chronic bronchitis or chronic diarrhea, and also "irritable ulcer" as well as old and sluggish ulcerations. I speak from personal experience, and after some eight thousand applications of cold over the spine personally made, with observation of the results. In all these forms of inflammation, as well as in chronic articular rheumatism, the spinal ice-bag is exceedingly grateful to the feelings of the patient, giving him a delightful sense of refreshment and rest. After a few weeks, or even a few days, he perceives a renewal of strength, particularly if he was originally strong and vigorous, which is surprising to him. In patients of naturally feeble constitution the results are longer in appearing.

The question which next arises is, what agent, force, or substance will so increase the function of the central nerve-cells as to give rise to inflammation at their peripheral terminals? The only reasonable reply is, that within the body the blood carries to all organs and tissues their proper nourishment, and that when in secreting organs, such as glands, there is an excess of blood, something beyond the normal supply, there will be excessive secretion from them; in other words, their functional action is increased. Muscular exercise, causing an increased flow of blood to the muscular system, will so add to its functional power that it soon can double its usual work. This

is well illustrated in the training of athletes, and I consider it a very reasonable hypothesis that excess of blood circulating in certain central cells of the cerebrospinal nervous system may so over-develop their functional power as to give rise to inflammations in the locations innervated and controlled by the hyperemic nerve-centers. It is entirely upon this hypothesis, that I have now for years successfully dispersed congestions, checked hemorrhages, and subdued inflammations, both acute and chronic.

Let us consider the morbid anatomy of acute articular rheumatism. "The synovial membrane is usually injected; the capillaries are dilated, and the reddening is best marked where the membrane joins the cartilage. The cells of the synovial fringes multiply; the epithelial cells are enlarged and often surrounded by fat. The lymphatics of the synovial adventitia are enlarged, the cartilage cells proliferate and the fundamental substance segments." (Loomis.) Here is practically an inflammation, with the usual heat, pain, and swelling. In chronic articular rheumatism the same changes occur, only with subacute symptoms.

All of these changes in the chronic form of rheumatism can at once be checked by applying cold over the spinal region, and not only checked, but a reverse process substituted, and absorption of the inflammatory products induced. I completely cured one of the worst cases of chronic articular rheumatism that I have ever seen by the application of the spinal ice bag alone, without the aid of drugs, after almost every other known remedy had been tried. Nearly every joint in the patient's body was affected, and had been so for eighteen months previous to my treatment. The pain was constant, night and day, and he had become much emaciated. He was able to crawl at a snail's pace by the aid of two canes, and after he had seated himself, it required at least a minute and a half for him to regain the erect position. His appetite had begun to fail, and he was rapidly going down hill. A twenty-two-inch spinal ice-bag was applied from the fourth cervical to the third lumbar vertebra, for one hour twice a day, with immediate relief to the pain while the bag remained on. In ten days pain had ceased in all his joints, and he could rise from the sitting position at once, easily and comfortably. His progress toward recovery was steady and rapid, and he regained in a few months about forty pounds in weight. In six-months' time the cure was complete, and from that day to the present (some twelve years) he has had no relapse to my knowledge.

The cold over the spine induces these great and vital changes by expelling from the hyperemic trophic vasodilator nerve-centers that supply the joints the excess of blood, which, by increasing the function of the centers, caused the inflammation in the joints. This excess being expelled, the inflammatory process at the nerve terminals must cease.

Further, by the power of the spinal ice-bag to dilate the whole arterial system, the general circulation and consequently the general nutrition is improved, the abnormal supply of blood within the joints is withdrawn from them and distributed to every tissue and organ in the body, filling with new life and vigor anemic muscles, and stimulating healthy secretion and excretion from the viscera. This augmentation of all metabolic processes creates a call for more oxygen, and in all cachectic conditions the respiration is invariably deepened by the use of the spinal ice-bag. I could cite cases of a number of patients treated successfully, but I desire rather to set before the profession the view of rheumatism as an inflammatory affection due to a hyperemia of a certain class of nerve-centers, in order that others may test the action of the ice-bag in the chronic form of articular rheumatism.

I do not advise the use of the spinal ice-bag in acute articular rheumatism, on account of the great shock to the system in the sudden checking of such widespread disorder, but after the disease has run its course, the condition of the patient may be improved much more rapidly and the strength more speedily regained by the use of cold over the spinal nerve-centers, than is possible without such treatment.

In lumbago, that very painful form of muscular rheumatism, the dorsolumbar spinal ice-bag (ten inches long, four and a quarter inches wide) will readily break an acute attack, with almost immediate comfort to the patient. At the same time a fairly strong cholagogue should be administered, for in the majority of acute attacks of this complaint digestion is disordered and the liver is very inactive. In chronic lumbago the ice-bag will effect a cure in many cases, and in others it will check the severity of the disease, and give much ease to the patient.

In chronic articular rheumatism the spinal ice-bag may be used from one-half an hour to three hours per day in divided applications, according to the strength and general condition of the patient. If the appetite be good, and the patient fairly strong, then the ice-bag, at first wrapped in one thickness of flannel, may be used morning, noon, and night for an hour, but the physician must exercise judgment, and make the treatment either strong or light according to the strength and natural vital power of the patient. He must also keep the bowels moving steadily and naturally, for when new vigor is suddenly imparted to the whole organism, the secretions from the digestive organs are largely increased, much

more food is consumed, and if care is not taken to evacuate the whole intestinal tract regularly and completely during the first few weeks of treatment, there is apt to be a good deal of trouble with the liver and the digestive secretions.

In an acute attack of lumbago it is my custom to evacuate the whole intestinal tract by a cholagogue pill and a large enema, and to apply the dorsolumbar ice-bag against the skin, and continuously, from the seventh or eighth dorsal to the third lumbar vertebra, until the patient is able to rise and move about with some degree of ease. I then re-apply the bag every four hours, for one hour at a time, until entire relief has been established. A mild tonic with some preparation of iron will then be sufficient to restore the patient to his usual health.

THE USE OF ANTITOXIN.

BY GEO. H. CATTERMOLE, M.D.,
OF LANSING, MICH.:
CONTAGIOUS DISEASE INSPECTOR FOR THE MICHIGAN BOARD OF HEALTH.

THE following observations were made in the wards and clinics of the Berlin Charity Hospital during the winter of 1897–98, and are of interest because of the thorough test given antitoxin as a prophylactic and curative agent.

With a very few exceptions each child on entering the Charité was given a 500-unit inoculation of Behring's serum as a prophylactic against diphtheria. This precaution was taken regardless of what disease the child was suffering from on its entrance to the hospital, and without doubt was a wise measure in such an institution, judging from the fact that a number of cases of diphtheria occurred in the general wards of the hospital, usually about three or four weeks after the entrance of the patients. The prophylactic dose of antitoxin probably only gave immunity for three or four weeks, but as this is much longer than the average period of incubation in diphtheria it is reasonable to suppose that those patients developing the disease after remaining in the hospital for so long a time, must have become infected after entering the wards. As further evidence that the hospital was infected with diphtheria, three patients to whom the serum was not administered on entrance contracted the disease in from two to seven days after being admitted.

Children remaining in the hospital less than three weeks may have been protected from diphtheria by the immunizing dose of antitoxin, although many patients remained in the wards longer than three weeks without contracting this disease. A few patients who were admitted with other diseases, and who received the immunizing antitoxin, developed diphtheria after being in the hospital only a few (three to five) days, but in these cases there is the probability that they contracted diphtheria before coming into the hospital or immediately on entrance to the wards. Without exception these latter cases were of a very mild form, and in this respect show a close analogy to those cases of smallpox in which vaccination has been practised between the time of the exposure of the patient and the onset of the disease. We have good reason to believe that if antitoxins are introduced simultaneously with the toxins, or the toxin-producers, they will neutralize or modify the deleterious effects of the latter. Some interesting results along this line have recently been obtained by Wassermann of Berlin, who injected normal brain substance simultaneously with tetanus bacilli. The animals treated thus remained free from toxic symptoms while the control animals succumbed to the disease. Wassermann explains this by the fact of the toxin combining with the injected brain substance and not affecting the nervous tissues of the animal. In a similar way antitoxin probably neutralizes the poison elaborated by the Klebs-Loeffler bacillus if given before the toxin from the bacillus has had time to poison the nerve-cells and other tissues. In evidence of this statement the following history of a case, in which the antitoxin was probably given too late, may be of interest:

A boy, aged thirteen years, suffering from a severe attack of diphtheria, was admitted to the hospital on the fourth day of sickness. Membrane covered the free edge of the soft palate and both tonsils. He was given Behring's serum on entrance to the ward. His temperature rose for two days (or until the sixth day of illness), after which it began to decline and at the end of the second week was normal. On the twenty-third and twenty-fourth days his temperature rose again, probably due to the development of otitis media. From this time symptoms of paralysis began to appear, involving the soft palate, legs, muscles of the back and muscles of accommodation, while those of the arms were less affected. In this case the serum, given on the fourth day of sickness, was probably too late to prevent the action of the poison upon the nerve-cells, and the subsequent paralysis. He recovered after a prolonged convalescence.

The earlier antitoxin is given after the disease is contracted, the more effectual will its action be. Here is where the private practitioner should act promptly. When administered on the first day of the disease probably all patients recover; on the second and third days the results are not so good, and later than the third day antitoxin may have no beneficial action, as the system is already poisoned. It may even do harm when given too late in the disease.

When children have been exposed, a prophylactic

dose of the serum should be given at once. I am inclined to favor the use of the stronger (concentrated) serums, both for prophylaxis and curative actions, as their use seems to be more certain and followed by fewer cases of serum erythema. This erythema appears one or two days after the administration of the serum and resembles that of scarlatina, but in color is a trifle darker, and is not accompanied by such high temperature. With this erythema there is likely to be greater swelling of the cervical glands. Heubner thinks the erythema is a serious complication and that it may be due to impurities in the serum. Certain it is that patients having this complication are more likely to develop the septic form of the disease. The best explanation of this seems to be that the longer the true diphtheria germ or poison acts on the tissues the more likely there is to be mixed infection. The Klebs-Loeffler bacillus develops more rapidly than the streptococcus, and so prepares a culture-ground for the latter germ. The early use of *good* serum retards the formation of membrane and lessens the chance of mixed infection, but if erythema follows the use of the antitoxin it prolongs the illness and seems to favor the growth of the streptococcus. The following history is a good example of this:

A seven-year-old girl was taken sick, October 23d, with true diphtheria, as shown by the growth of the Klebs-Loeffler bacillus on blood-serum. She was given antitoxin by a physician in private practice (strength not learned). A few days later erythema appeared, due to the use of the antitoxin. At this time she was admitted to the hospital. The cervical glands were enlarged and the case resembled scarlatina, but lacked the high temperature and subsequent appearance of that disease. At the end of the second week the temperature rose to 40° C. (104° F.), and fluctuation was noticed in the glands on the right side of the neck. These glands were lanced, and streptococci were found in the abscess. A few days later Klebs-Loeffler bacilli were found in a membrane which formed on the wound. In the fifth week dulness appeared over the right lung. This was tapped and the fluid found to contain streptococci. They were not pneumococci. Ten weeks after the first sickness an abscess formed over the left shoulder-blade.

This was considered a case of septic infection. The first attack was pure diphtheria, but its cure was delayed by the erythema, and this delay gave the streptococcus time to develop, with subsequent spread of the septic disease.

Serum erythema is the most serious complication that I have observed resulting from the use of antitoxin, but it is not of sufficient importance to make one hesitate for a moment in the use of antitoxin. All reports of its use are favorable. The general use of antitoxin as a prophylactic during an epidemic, and its careful but thorough use in all cases of the disease, would, I believe, reduce the deaths from diphtheria to *nil*.

WAR ARTICLES.

CARING FOR THE SICK AND WOUNDED AT CAMP WIKOFF, MONTAUK POINT, LONG ISLAND.

BY J. H. BURTENSHAW, M.D.,
OF NEW YORK.

ACCORDING to some authorities, no more ideal spot could have been chosen as a site for a military camp than Montauk Point, at the extreme eastern end of Long Island, for the ground is rolling, pasturage for the horses and mules is abundant, and 100,000 men might easily find tent room on the four-mile stretch between sea and sound without crowding. On the other hand, it is claimed that the site is too far removed from the several bases of supply, the ground is not sufficiently level, there are too many marshy places in the hollows, and, above all, there is a lack of wholesome water both for drinking and cooking purposes. The last objection, at least, promises speedily to be overcome, and it is safe to assume that when the 20,000 troops shall have arrived from the various mobilization camps in the South and from the vicinity of Santiago, they will quickly recuperate and forget the hardships of the past.

The regulations which have been adopted in connection with the landing of the troops show admirable forethought, and every precaution will be taken to prevent infection. Quarantine measures on the transports are under the charge of Passed Assistant-Surgeon G. B. Magruder of the Marine Hospital Service, assisted by Passed Assistant-Surgeon J. J. Kinyoun, Assistant-Surgeons Hastings, Tabb, and White, and Acting Assistant-Surgeon Brunner. Under these officers is a staff of three hospital stewards and ten hospital attendants. All transports will be boarded immediately upon arrival in the bay by Dr. Magruder, who will determine whether the soldiers on board should be kept in strict quarantine or simply disinfected. The yellow flag will be hoisted at the time of his visit, and no communication whatever allowed with the shore until the inspection has been completed and the final disposition of the troops determined upon.

There are two piers jutting out into Fort Pond Bay, one above and the other below the railway station, there being a sufficient depth of water at the end of each to allow of the transports making a landing. The men on ships having a clean bill of health will be landed at the lower pier, and after

their clothing has been disinfected and each man has taken a bath, will be allowed to move into the general camp. All troops coming from Cuba will be provided with complete, new outfits of clothing in order to lessen the danger of contagion. Ships reporting illness on board will be required to land at the upper pier, where is moored the disinfecting barge "Protector," recently brought from Philadelphia. This vessel in many respects is a counterpart of the one in use at the Port of New York, having a large chamber for disinfection by means of formaldehyd, another in which sulphur is used, a steam chest, bichlorid tank, four shower baths, six bath tubs, water-closets, laboratories for the examination of fluids, excreta, and the like, and a crematory. Here all the men from these ships will be required to take a bath, they will be supplied with new or disinfected clothing, and then will be removed to the detention camp, where they will remain for a period of from five to seven days under observation before being permitted to go to the general camp. Dr. Magruder and his assistants will be able to provide for the bathing and disinfecting of 100 men per hour, and it is calculated that at least 18,000 of the troops will undergo this process on board the "Protector." All those suspected to be suffering from contagious disease, especially yellow fever, will be sent to the isolation camp, there to remain until the disease from which they are suffering has been diagnosed, or until all danger of contagion is past, when they will be removed to the general hospital. It is probable that all the men suffering from typhoid fever will at once be taken to some one of the hospitals in New York City, in accordance with a suggestion recently made by Dr. A. H. Doty, Health Officer of the Port of New York. A special camp for the treatment of yellow-fever patients has been established, but in the opinion of Assistant Surgeon-General Forwood and Surgeons Magruder and Brunner, it will not be necessary to make use of it, as there is little probability of the disease being brought to this part of the country, even by those coming from the infected district in the vicinity of Santiago.

The detention camp is located about one and one-half miles from the piers and from the railway station, and the same distance from the general hospital. It nestles in a broad valley out of sight from the main thoroughfare leading to the general camp, and is reached by a new road which has just been cut. At present there are about 150 tents in position, but this number will be increased indefinitely as occasion demands. This camp, as well as the isolation and yellow-fever camps, will be subject to the strictest quarantine, and no visitors will be allowed to approach them. Sentries have already been posted on all sides, and at the point where the new road branches off, so there will be little difficulty in maintaining the regulations. The isolation camp is situated three-quarters of a mile from the detention camp, and a mile and one-half or more from the general hospital, also in a secluded spot, and the tents designed for the use of yellow-fever patients are about half a mile further on, at the most distant end of the encampment. Ten ambulances are at present on the ground, and twice this number are expected to arrive within a few days. Ambulances used in transporting men suspected of suffering from contagious disease will be carefully disinfected before again being used.

The general hospital is located on a broad plateau overlooking the ocean on the south and the rolling hills of Montauk on the north, and at present is one and one-half miles from the nearest cavalry or infantry encampment, although as the troops arrive they probably will be assigned to locations somewhat nearer. Too much praise cannot be given to Colonel Forwood and Dr. Ira C. Brown for having overcome difficulties which would have staggered men of less force and ability, for in less than one week they planned and erected the largest and most complete hospital of its kind ever seen in this country. Dr. Brown, who was surgeon of the 6th Cavalry Regiment before being detailed to duty at the general hospital, recently brought thirty-five sick troopers from Tampa to Montauk in a freight-car devoid of comforts or conveniences, most of the men being ill with typhoid fever, and landed his patients at the camp in better condition than when they started. Such a feat is one to be proud of, but the conscientious surgeon decreased in weight by fifty pounds in doing it.

The arrangement of the entire hospital is admirable in every respect, and it will indeed be a very sick patient who is not quickly restored to health and vigor under the influence of these surroundings. At the extreme right, or western end, on slightly elevated ground, are fifteen 12x12 tents occupied by the hospital officers, and a short distance to one side are their mess and kitchen-tents. Fifty feet removed from and in front of the officers' quarters, adjoining the hospital wards, are four rows of three tents each, erected on wooden platforms measuring 14 feet 6 inches by 42 feet, there being two tents to each platform, and each pair separated by a "fly" of the same size as a regulation tent. The first two on the right are devoted to the general offices, the second two to drugs and hospital supplies, and the third two to anesthetizing and operating purposes. On the left are, first, the commissary and quartermaster's supply

tents, then those containing medical stores, and, finally, the executive office and dispensary.

An open space, measuring 24 feet 6 inches, separates the executive office and operating-tent from the hospital wards. Extending for a distance of 245 feet from this line is a wooden platform, 14 feet 6 inches wide, and raised two feet from the ground, and at right angles to this, at intervals of fifteen feet, are sixteen platforms, eight on each side, 14 feet 6 inches wide and 112 feet long, upon which, on wooden framework, the wall tents for the patients have been erected. The long platform is covered over its entire length with canvas, and it thus affords a pleasant lounging-place and promenade for those invalids who are able to be up, and their visitors. The hospital tents on each platform are arranged in pairs and each pair is separated from the next by a "fly" with open sides, thus affording ample ventilation. Each tent is of the regulation size—14x14.6—and the intervening space between each two pair measures the same. There are six tents and two "flies" on each platform, or ninety-six tents in all, and each accommodates five patients, or a total of 480, without crowding. On one side of each tent three beds are placed side by side, and, on the other side two, end to end, thus allowing ample room for a passageway. If occasion requires these wards will accommodate an additional hundred patients, and still give each one plenty of room. The iron beds are of an improved pattern, and may be folded up. Each is supplied with wire springs, two pairs of blankets, a feather pillow, and sheets and pillow case. Portable commodes are in each ward.

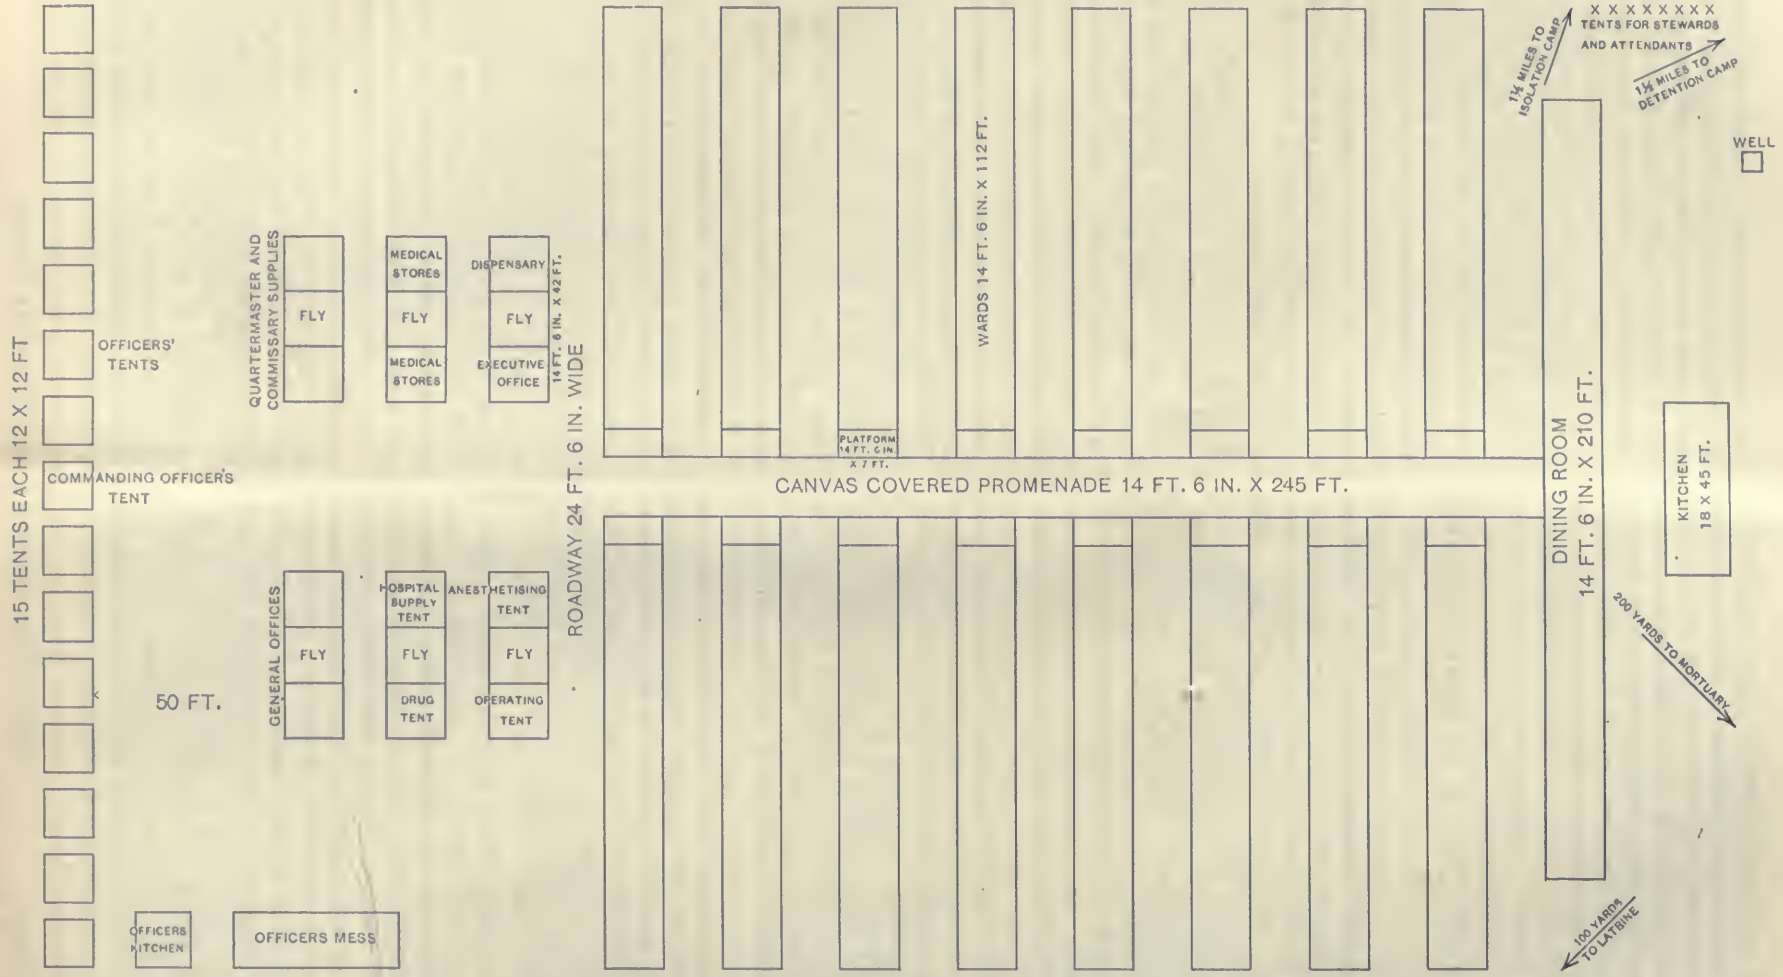
Each ward and bed in the hospital is numbered and an indexed list of all patients is kept by Dr. Brown. A morning and evening report is made to him by the assistant surgeons of the condition of every patient in the wards, and these reports are filed away for future reference should this be necessary. An ambulance bearing a sick or wounded soldier is driven to the executive office at the end of the row and, if practicable, the patient's history is taken by one of the assistants, and he is then carried to one of the wards on a stretcher. At the time of my visit (August 12th) there were ninety patients in the hospital, fifteen having been discharged and ten admitted that day. About seventy per cent. of these were suffering from chronic diarrhea and dysentery, contracted at the camps in the South. There were seven cases of typhoid fever, all in the last stages, and the patients were rapidly convalescing. Not a single case of contagious or infectious disease up to that time had developed among the 3500 troops then in camp.

It is not likely that a patrol will be established around the quarters of the general hospital, as this step is considered unnecessary, but care will be taken that the patients are not fatigued by too much attention on the part of visitors, and the hours at which the latter will be permitted to enter the hospital will be limited. The Red-Cross Society and the Women's National War Relief Association have established headquarters there and clothing and delicacies of all kinds are abundant. When I asked Colonel Forwood if anything else was needed his reply was characteristic. "If we were to accept all offers of assistance," he said, "we would have to put up a storehouse as big as the hospital itself. We want the New York daily papers, the magazines, and the pictorial weeklies—all these and more, but we *don't* want any more jam and pajamas. The commissary tents, medical supply-tents, and even the tents of the officers are bulging with jam and pajamas, and still they come by every train." It is to be hoped that the many war relief societies throughout the country will take the hint.

Miss Helen Gould has supplied the patients with an unlimited quantity of mineral and other waters, and has given Dr. Brown authority to order anything else that may be needed at her expense. The question of diet for the sick was of such importance that it received attention at the very beginning, and it was proposed to erect a special diet-kitchen for the purpose of preparing the food, but the matter has been simplified by Colonel Forwood, who has set aside a large cooking-range in the general kitchen for the exclusive use of two experienced cooks, who are to be installed by the Womens' Relief Association, and the same organization will also furnish all necessary supplies for this purpose.

At the eastern end of the hospital is a platform upon which is the general dining-room, access to which is gained from the long covered promenade before mentioned. This room is 14 feet 6 inches in width and 210 feet long, and is divided into sections of three tents and a "fly" throughout its length. Here the convalescents and hospital attendants will take their meals. Twenty-four feet to the rear of this structure is the hospital kitchen, 18x45 feet, which has a brick floor and, at present, two modern cooking-ranges, with room for three additional ones if their use becomes necessary. The mortuary is temporarily located about two hundred yards from the dining-room, but its position is soon to be changed.

The sink, or latrine, at the hospital is crude in construction and entirely inadequate to the needs of the inmates. The plans and specifications of the latrine devised by Dr. John McG. Woodbury, the present chief sanitary inspector of the army in Porto Rico, which were recently forwarded by the MEDICAL



GROUND-PLAN OF THE GENERAL HOSPITAL AT CAMP WIKOFF, MONTAUK POINT, LONG ISLAND.
Erected under the personal supervision of Colonel W. H. Forwood, Assistant Surgeon-General, United States Army.

NEWS to Dr. Brown, undoubtedly will result in the remedying of this defect immediately. The contract has just been let for a steam-laundry plant, 30 by 60 feet in size, which is to be erected for the use of the hospital at an expense of $2500. It will be located nearly one mile from the hospital site, and will be of sufficient capacity to wash the bed and body linen of 600 men per day. Fresh water for its purposes will be obtained from Fort Pond, and drainage will be into the ocean.

At the present time the working staff of the general hospital, in addition to Colonel Forwood and Dr. Brown, is made up of three very efficient acting assistant surgeons—Drs. F. G. Jones, C. E. Moore, and Moons—thirty-one orderlies, one steward, one assistant steward, one cook, and one assistant cook. One hundred additional orderlies have been asked for, and the kitchen force will also be increased. Dr. Brown has proved himself such a capable and painstaking officer that the wisdom shown in his selection for this important post is very apparent.

The purity of the water-supply of a camp is all important, and grave doubts have been expressed by experts as to the possibility of procuring palatable and uncontaminated water at Camp Wikoff. Two small lakes—Fort Pond, near the railway station, on the ocean side of the camp, and Great Pond, near the Sound—have been depended upon to supply water for both drinking and cooking purposes, but the former contains 158 grains of salt to the gallon, and the latter 210, so that the water is decidedly brackish. Aside from this fact, the camp of the 9th Cavalry has been pitched at the border of the first named, and that of the 6th Cavalry by the second, and as the horses and mules belonging to these troops, as well as a majority of the 2000 other animals at the camp, are led down to the ponds twice daily for water, the supply will very soon become unfit for use. A pumping-station has been established at the edge of Fort Pond, from which a pipe-line conducts the water to different points, but the in-take of the station is located but a few feet from the shore, which adds to the danger. Orders have been given that all the water taken from the ponds must be boiled before being used, but it is hardly to be expected that this will be done. All water used at the general hospital and detention camps is brought in tank-wagons from the railway company's well at the station, and is supposed to be pure and wholesome.

Wells are being sunk in different parts of the camp, and the contractors expect to obtain an output of at least 200,000 gallons of pure water daily for the use of the troops. If their expectations are realized this will allow of but ten gallons a day to each man, and the horses and mules, 10,000 of which are expected at the camp, are not provided for in the estimate In New York City the water-supply is equal to eighty-three gallons per capita daily, and it will be seen at once that unless other provision is made the supply at Montauk Point will prove entirely inadequate. Experts have expressed the opinion that it is impossible to obtain water on Long Island in any quantity that is free from surface impregnation or seepage from the salt water or marshes, and have instanced the many years of fruitless experience in endeavoring to increase the supply for the City of Brooklyn. It will be remembered that Baisley's Pond, one of the largest sources of Brooklyn's supply, and also Spring Creek, both in Jamaica, had to be shut off three years ago because of the absolute unfitness of their water for city use. It has been said that the geological formation of the island is such that all water below the surface is contaminated by surface drainage, and in proof of this the many analyses that have been made are referred to.

Colonel Forwood is inclined to disagree with these conclusions. He claims that at Montauk Point there is, first, a moderately deep layer of rich, black earth, then a stratum of tenacious clay, ranging from six to eight feet in thickness, and, finally, from twenty to fifty feet of coarse sand and gravel, and that a well sunk to a depth of from twenty-four to forty feet, bricked and cemented to keep out surface drainage, will supply perfectly pure water. If good water is found in the wells that are being sunk in the vicinity of the pumping-station the in-take pipes will be transferred at once to the new source of supply, and the pond water will no longer be used. The situation of the well that is being sunk near the general hospital has not been well chosen. It is removed but a few yards from the kitchen, is on a lower level, and is close to a small bog. It is probable, however, that even if passably good water is found at this place it will be used only for cooking purposes, and that the drinking-supply will continue to be brought from distant points.

FOOD AND RAIMENT IN THE PHILIPPINES.

BY JOSEPH EARLE STEVENS
OF BOSTON.

THE dinner one used to get for 35 cents at the Manila Club did not begin to seem as strange after United States fare as did one's first home meal taste heavenly after a couple of years in the Philippines. For on the outward journey to the Far East the traveler gets used to finding the food growing poorer and scarcely notices the drop in quality between that served on the steamers running over from Hong Kong and that which he finds at

the English Club. Although a dose of the bill of fare at the Hotel Oriente in Manila, with its early breakfast of thick chocolate, with its lunch of fish, eggs, cheese, and bananas, and its dinner of soup, "puchero," chicken, and boiled goat rarely failed to instil a Spanish flavor into the breath of the freshly arrived traveler, yet the club table was good enough not to be noticeably worse than that in Yokohama and Hong Kong. Peculiarly enough, however, when one retraced his steps and started homeward the change seemed prodigious, and a first meal in the Hong Kong hotel, or on the "Coptic," or at the Grand in Yokohama, tasted so supremely far above Manila fare that one was consoled for having eaten a long series of Philippine meals by the overwhelming pleasure of once more getting fresh celery, good beef, new peas, and pie.

Cattle don't thrive in the Philippines. Sheep are not found there. Potatoes don't grow in the Archipelago. Vegetables are everywhere scarce, so it seems, and the peas and asparagus one gets come mostly from France or Germany. In peaceful times, gone by—to be sure—the industrious Chinaman in his little garden raised delicacies for the tables of foreigners, but now that most of these almond-eyed celestials have retired with their dollars to China, tomatoes, lettuce, beans, and corn, are probably scarcer. Chicken and eggs are two great Philippine standbys, and always seem to form a groundwork to every meal. Beef from poor wornout bullocks, shipped up from Australia, likewise has its usual bright place to fill, but mutton and potatoes have to come over from China. Fruits, Manila has in plenty, and what with mangoes, mangosteens, oranges, bananas, pineapples, grape fruits, and melons selling for a song, the market is well supplied.

The meal hours of the foreigner in Manila are somewhat curious. The "desayuno," or light breakfast comes at 7.30; tiffin, or hearty breakfast at noon; afternoon tea —a peculiar institution everywhere observed—at 4, and hearty dinner at 8 P.M. Thus, one goes until noon on not more than an egg or two and a bit of fruit, and eats so much at tiffin in consequence, that, together with the rest of the town, he has to lie off in a long chair for an hour or two in order to acquire energy enough to return to work. But it is thoroughly advisable to follow the local custom in taking the siesta during the middle of the day and, as all Manila seems asleep between 12 M. and 3 P.M., one soon acquires a habit that is hard to get rid of after a return to the more hurried days in the Western World.

Tea comes along conveniently at 4 P.M., and all the big offices have their tea-room. Toast, fruit, and jam, play their part and business gossip is always reserved for just this occasion. With the home dinner at 8, one gets a chance to enjoy, out of doors, the cool season which surrounds the sunset, and is generally ready to go to bed shortly after the last meal of the day has been finished.

All meat in Manila and other parts of the islands is eaten fresh-killed, since ice fails to preserve fish, flesh, or fowl, and game and fowl are always sold at the markets alive. It is not to be denied that the tough, stringy taste to this portion of the menu is far from desirable, but necessity seems to know no law and one must accustom himself almost to seeing the chickens for his fourth course wandering around in the kitchen half plucked as he begins his feast.

Living was very cheap in Manila during my stay, and our cook got but 40 cents with which to provide the dinner for four people. And we would have such dishes as soup, fish, chops, and peas, roast chicken with potatoes, beans, and corn, salad, dessert, and fruit—quite a repast for so small a sum.

The milk available in the Philippines rarely comes from the Jersey cow, but is a product of the "carabao" or water buffalo, and tastes somewhat oily. Oatmeal and cream are things unknown, and the former is now said to be too heating for a hot climate diet. Chocolate seems to come under the same category, and even mangoes—that fruit with the smooth, turpentine taste—have to be eschewed by him who suffers from prickly heat. Bread, too, is not eaten so much as toast, and the foreigner almost always insists on getting his "pan tostada" in order that any lurking microbes, which the bread may have absorbed during the process of manufacture in the little Chinese bakery, may be destroyed.

As the Manila water-supply was good I had no hesitation in drinking plenty of Adam's ale and never found it disagreed with me. In fact, some of the old stagers say a long glass of water just after one gets up in the morning doeth good like a medicine, and suffice it to say, it seemed to work like a charm in my case. Needless to remark the members of the small English colony, which did not number more than three score and ten, all drank whisky, and many of them insisted that unless one took just so much of that article each day he would surely get the fever. Brandy has been given up in the East as a regular beverage, for it seems to have been the cause of much liver trouble and, whereas, thousands of cases of brandy used once to be sent out to India, China, and the Philippines, whisky has now stepped in and taken its place. Strong claret is the popular beverage with the Spanish element, and sweet "licores" with the natives. Most excellent beer is to be had on draft at the "cervezerias" along the Escolta, and the Manila brew has quite a famous reputation.

In conclusion, as to food it must be said that, in peaceful times, Manila fare is not bad, though it lacks variety, and such articles as one gets in the ordinary menu at the club, or in the restaurants seem amply to supply the demands made on the new arrival by the climate. Heavy or heating foods, such as oatmeal, baked beans, plum puddings, chocolate, and the like are best left alone, and in my mind the less alcohol one takes the better. Claret and seltzer make one of the cleanest drinks to be imagined, and one better than a brandy and soda, or something of the same strong make-up.

When I went to Manila I took several suits of light clothes, but failed to use one of them during my two-years' stay. Even the thinnest garments made in the States seem too heavy for the climate of the Philippines, and it is far wiser, in ordinary times, to go to Manila with but clothes enough to serve for the cool weather

of the journey. Plenty of handkerchiefs, light undershirts and socks may well form part of one's wardrobe, but beyond that it would generally be as well to let a Hong Kong or Manila tailor fit one out with the light and airy costumes of the country. These suits are made of thin, white sheeting, and some of them consist of but two pieces—a light button-up military jacket and pair of trousers. Others have the ordinary open-front jacket, and whereas—dressed in the first costume—one need not wear shirt, collar, or tie; in the second he has to be provided with all of these. The button-up—as it is called—is best for hot work in the office or in the sun, and the open jacket is more suitable for the promenade or a dinner at the club. Thin, white dress coats, without tails, are also in vogue, and a Tuxedo coat, with white sheeting trousers, is all right at a dinner party. Drawers are not generally worn, but in their stead comes the flannel cholera belt which protects the stomach from exposure to sudden drafts. A fresh suit is worn daily by the regular resident, and fresh socks and fresh underwear. One needs about eighteen of these white suits to have plenty for daily use and an extra change on Sundays or feast-day occasions, and as the laundryman used only to charge $2.50 a month for washing all that one wished to throw in the hamper, the question of expense was merely the initial one at the tailor's.

Felt hats are in vogue, as a rule, with the European colony, but now and then a Panama is visible. As before said, the great point is to have the headgear thick enough to keep the sun from penetrating the hat material and to see that it somewhat protects the back part of the neck. Pith helmets and sun hats are always advisable for use in the heat of the day or for trips to the provinces, and because the natives go bareheaded is just the reason why the foreigner should not do so. Thus to conclude, as food is cheap in Manila, so is dress, and the white suit should not cost over $2.50. One never feels so cleanly as when after his bath each morning he puts on an entirely fresh set of garments, and at night it is a positive relief to feel that you can thoroughly shake off the day's impressions by thrusting your moist clothes into the hamper presided over by the "lavandero." A native servant is, of course, invaluable to look after one's wardrobe, and if at the start he is made responsible for everything his master entrusts to his care, he generally sees that nothing goes astray.

Scarcely anywhere in the tropics can people dress as cheaply and live as cheaply as in Manila, and if that were the end and aim of life we should see boat-loads of wanderers going to the Philippines. But, in my mind, very few Americans will ever be content to settle permanently in the Archipelago and, like myself, will be glad to feel they are only transients.

Sanitary Inspector at Santiago.—Sanitary Inspector H. S. Caminero, United States Marine Hospital Service, who before the inauguration of hostilities with Spain was on duty at Santiago, and who since that date has been at Kingston, Jamaica, has resumed his duties at that port, and will have full charge of the quarantine service there.

AMBULANCE DRILL WITH SWORD SIGNALS—DISTRIBUTION OF PERSONNEL AND MATERIAL ON MOBILIZATION.

By HENRY I. RAYMOND, M.D.,
MAJOR AND BRIGADE SURGEON, UNITED STATES VOLUNTEERS, COMMANDING AMBULANCE COMPANY.

THERE are few exercises more exhilarating in the early morning air than mounted drill with a train of ambulances guided in their movements by sword signals from the officer in charge, with the immediate translation of the signals by the ambulance orderly—a smart, bright young fellow, quick of apprehension and of good lung power—who sits beside the driver on the box with arms folded, eyes clinging to the signal sword, and all alertness in look and actions to cry the signals back to the succeeding ambulance, sixteen feet in the rear, and so on till the rearmost orderly, catching it up, sounds it in the ear of his driver whose eyes are bent upon the roadway ahead and upon his fractious mules, his ears open to the several commands, "right by ambulance, march," "trot," "gallop," "decrease speed one degree," "on right into line, march," "halt," etc.

More than one tail-gate has been battered by the oncoming pole of the ambulance in the rear, in obeying on the trot or gallop down hill a badly timed signal from the instructor to decrease one degree (gallop to trot, trot to walk), and similar occurrences are likely to take place on level ground when the proper intervals—sixteen feet—between ambulances in column are not rigidly observed. And yet the ambulance company must train to go on the double-quick, for much of its utility depends upon celerity of movement and precision of action in getting to the front and handling the wounded with expedition and care. To approximate this degree of perfection demands training—repetition of the action under conditions approximating actual service upon the battle-field as nearly as practicable. To this end, also, ambulance drills are conducted ofttimes on drill-grounds or commons occupied simultaneously by companies or battalions of the regiments of the divisions at the early morning drills or exercises.

The ambulance companies of this corps are now organized in accordance with Circular No. 3, from headquarters, 3rd Army Corps, Chief Surgeon's Office, making the following distribution of personnel:

	Brigade Hdqrs.	Sections. 1st.	2d.	3d.
Six Medical Officers:				
1 Medical officer, commanding	1	..	..	..
1 Medical officer, executive	1	..	..	..
1 Medical officer, subsistence	1	..	..	..
3 Medical officers, attending surgeons	..	1	1	1
1 Quartermaster, Lieut. of the line	1	..	..	..
Ten Non-Commissioned Officers:				
1 Hospital-steward (1st. sergt.)	1	..	..	..
2 Hospital-stewards (Ambulance sergts.)	..	1	1	..
1 Hospital-steward (Dispenser)	1	..	..	..
1 Hospital-steward (Q. M. sergt.)	1	..	..	..
2 Hospital-stewards (Bearer sergts.)	..	..	1	1
1 Acting-steward (Commissary sergt.)	1	..	..	..
1 Acting-steward (Bearer sergt.)	..	1	..	..
1 Acting-steward (Records)	1	..	..	..
1 Trumpeter	1	..	..	..

	Brigade Hdqrs.	Sections. 1st.	2d.	3d.
2 Cooks	1	..	..	1
2 Assistant Cooks	..	1	1	..
25 Ambulance drivers	1	8	8	8
38 Litter-bearers and attendants	1	12	12	13
25 Ambulance orderlies	1	8	8	8
5 Orderlies	2	1	1	1
4 Wagon-drivers	1	1	1	1
1 Blacksmith	1	..	..	..
1 Saddler	1	..	..	..
	19	34	34	34

It is stipulated that at least one section will always be with headquarters. As to material, it is provided that blacksmiths' and saddlers' tools will, as far as practicable, be carried, each set in a specially prepared chest, with headquarters' equipage. Other camp equipage and material is equally distributed among the three wagons (one for each brigade section) so that what pertains to the dressing station, including hospital flags and National flags with halyards and poles, will be carried by the respective brigade section wagon.

In camp the men have been provided with conical wall-tents, accommodating from fifteen to eighteen to the tent, but on the march "the men will occupy shelter-tents in which, when struck, they will roll a rubber blanket and their clothing, and which will be carried in the wagons of their section." Rations, forage, and officers' baggage are distributed as follows:

	Brigade Hdqrs.	Sections. 1st.	2d.	3rd.
5 Days' rations (114 men)—lbs	428	428	428	428
5 Days' short forage (81 animals)—lbs	911	911	911	911
Officers' baggage—lbs	450	150	150	150

Medical supplies, hospital stores, antiseptics, medicines, etc., are carried in the ambulances and so distributed that ambulances 1 and 5 of each eight ambulances pertaining to a given section will carry medicines and medical supplies, while 2, 3, 4, 6, and 7, will carry hospital stores.

Circular No. 3, above referred to, itemizes all material supplies both in the medical and transportation departments of the ambulance company, and closes with the following paragraphs:

"All the material herein laid down will be provided, and so much of it as is not needed for current use will be kept separate and packed in such a manner that the ambulance company, or any part of it, can be mobilized at the shortest notice.

"The company will be frequently practised in pitching and breaking camp, organizing dressing and ambulance-stations, and in such other work as it will be called upon to do on the march and battle-field. The officers, non-commissioned officers, and men must be assigned by name in written orders to the brigade sections and to their sections on the battle-field.

"Every man of the ambulance company will be properly uniformed, will wear leggings, and be equipped with canteen, haversack, and belt.

"A designated number of men will wear the hospital corps litter-sling and orderly pouches herein provided."

CLINICAL MEMORANDUM.

A CASE OF OTITIC BRAIN ABSCESS (FROM CHRONIC OTORRHEA); OPTIC NEURITIS; OPENING OF THE MASTOID AND SKULL; RECOVERY.[1]

By FRANK S. MILBURY, M.D.,
OF BROOKLYN, N. Y.;
LARYNGOLOGIST, OTOLOGIST, AND OPHTHALMOLOGIST TO THE BEDFORD DISPENSARY AND HOSPITAL, AND TO THE NORTH BROOKLYN EYE, EAR, AND THROAT HOSPITAL.

ON May 25, 1897, Mrs. J., aged thirty-three, came to my office, bearing a letter from Dr. James J. Bowen, requesting me to examine her and to render my opinion, at the same time stating that he believed a mastoid operation was indicated. As I could get no intelligent history from the patient I interrogated her sister, who stated that there had been more or less continuous discharge from the left ear since infancy, following scarlet fever. At this time it was extremely offensive. By the touch of a sound dead bone was easily perceived in the tympanum and posterior wall of the meatus which was swollen and bulged forward. The mastoid was edematous and very red. The entire side of the head was acutely sensitive to the most gentle pressure. Violent uncontrollable headaches had continued several weeks. Slight paralyses of the left side of the face and right arm and leg existed. Her past life seemed wrapped in complete oblivion, and it was almost impossible for her to put what thoughts she had into words, showing amnesic aphasia. Temperature, 100° F.; pulse, 115. Excessive vomiting on the least movement of the head, and nearly as much when lying down with the head perfectly quiet. The ophthalmoscope showed optic neuritis in the left eye, but the condition of the patient precluded any further examination of the eyes by the perimeter or otherwise. It is possible that there may have been hemianopsia. It was evident that mastoid necrosis and suppuration existed, with possible cerebral abscess and meningitis, and the sooner an operation was performed the better. Accordingly she was placed in the Bedford Dispensary and Hospital.

The next day, May 26, at 11 A. M., with the assistance of Drs. Bowen and Rickard, she was anesthetized, the head was shaved, and under the most careful aseptic precautions we incised the soft tissues, detached the lining membrane of the meatus, laying the ear forward, and retracted the posterior integument, giving a clear view of an extended field. The cortex in places was soft but no fistulæ or pus were visible on the surface of the bone. By cautious chiseling, the antrum was entered. With a probe I explored and found in every direction carious bone, which was easily removed by a sharp spoon, and nearly the entire mastoid was found to be involved. The antrum and large cell at the tip of the mastoid and smaller cells were filled with very foul pus. The lateral sinus came into view, but looked blue and healthy and was pulsating. A large sequestrum was removed from the posterior wall of the meatus, making a broad connection between the tympanic cavity and antrum. The posterior-superior wall, which was soft, was also

[1] Read before the New York State Medical Association.

removed, and the moment the brain cavity was entered pus welled out in large quantities. I enlarged the wound in the skull with a rongeur, and with a sound measured the depth and extent of the pus-cavity. Greatly to my astonishment the instrument passed in about 4½ inches, and I think the sinus had a diameter of fully an inch and involved a portion of the temperosphenoidal lobe. Dr. Arthur C. Brush, a well-known neurologist of Brooklyn, who was called in consultation, is of the opinion that the abscess was, in this case, formed by a localized purulent meningitis, the walls of which were formed by adhesions between the dura and the arachnoid. In other words it was an intradural abscess. He does not think it involved the brain-tissue proper to any extent on account of the rapid and complete disappearance of the symptoms after the pressure was relieved by the evacuation of the pus, which would preclude any destruction of brain tissue.

The position of the lateral sinus would indicate that it was situated above the tentorium, and the direction taken by the probe that it extended inward, forward, and downward; that is, along the superior border of the petrous portion of the temporal bone to, or even beyond, the median line. An abscess in this situation on the left side would, by pressure on the speech-centers, give rise to aphasia with or without paralysis of the muscles concerned in the movements of the face and in speech, on account of their dual representation, and the fact that the more highly organized centers are the ones which are first and most seriously affected. The right hemiplegia is easily explained by pressure on the adjacent capsule. The left facial paralysis was due to the local involvement of the facial nerve in its passage through the petrous portion of the temporal.

Two hours had elapsed in the tedious work and was well borne by the patient, but when we began we had little hope that she would survive the operation. The wound was flushed with a 1 to 6000 corrosive-sublimate solution, dusted with iodoform and dressed with sublimate gauze, a drainage-tube being put in place, and the whole covered with cotton and a roller bandage. She was put in bed at 1:30 P. M.; temperature, 101° F.; pulse, 125; extremities cold. Hot-water bottles were put at the feet and every two hours she was given an injection of strychnin and whisky. The after treatment was long and tiresome. Temperature at 6 P. M., 100° F.; pulse, 120, and at 8 P. M., 110° F. Extremities warm; reaction from ether good; vomited considerably; slept from 12:30 A. M. to 5 A. M.. Frequent vomiting continued for six days, or until June 2, and for twelve days thereafter the temperature varied from 99½° to 101° F.; pulse, from 80 to 120, sometimes weak and intermittent, and at other times full and strong. The patient could retain no food but was nourished by enemata. At the first dressing quite a quantity of pus came from the wound but it was odorless. During the first seven days she remained in a state of almost constant lethargy, uttering no sound and apparently recognizing nothing. On the eighth day when Dr. Bowen called her by name, asking her if she knew him, the response was by quite a firm pressure of the hand. On the ninth day, June 4, and for several days thereafter, when asked a question, the answer would be "no" or "yes, dear," placing her hand upon her head, at the same time giving utterance to the word "pain," but not conscious of what she was doing. On June 7th, when asked how old she was, she shook her head, indicating she did not know, but when told said "all right."

The wound healed kindly, and improvement continued gradually, but slowly, until a complete restitution of the mind and a disappearance of the paralysis of the face, arm, and leg resulted. The hearing in the left ear is, of course, gone, but her vision is now normal. At rare intervals she will say peculiar things, apparently not realizing what she is uttering.

I have been unable to discover a parallel case in literature and doubt if there is one. It was seen by a large number of well-known physicians, but none could understand the existing condition, and the greatest mystery of all is the recovery. Another peculiar feature is the fact of her being about four months pregnant, and through it all did not abort. The mental condition was probably due to the abscess and pressure on the brain, which occasionally occurs in such cases.

MEDICAL PROGRESS.

Effects on the Tissues of the Different Fluids Used in Surgery.—VAN DER VELDE (*Rev. de Therapeut.*, July 1, 1898) has drawn the following conclusions from a study of the effects of various fluids on the cells of the blood and the tissues. Plain distilled water alters the blood-cells at once, destroying many of them. In physiological salt solution even the most delicate cells preserve their appearance and their functions as well. The various artificial serums, so called, suggested by Hayem, Cheron, and others, and which contain in addition to sodium chlorid a certain amount of sodium sulphate or other salts, possess no advantages over the physiological salt solution, and exert a more or less harmful action on some of the cells. Antiseptic solutions, whether of bichlorid of mercury, carbolic acid, boric acid, permanganate of potash, formaldehyd, nitrate of silver, etc., are so destructive to the tissues that the effect of a drop of them is often visible to the naked eye. They ought, therefore, never to be used in fresh wounds or in serous cavities. And even in the uterus, as after a curettement, it is better to use the saline solution six parts per thousand to wash out the débris, for the shape of the cavity makes a perfect disinfection of its lining with a fluid an impossibility, and by using the saline solution the danger of poisoning is avoided.

The Increase of Cancer and Its Cure by Cataphoresis.—MASSEY (*Vir. Med. Semi-Monthly*, June, 1898) presents a table showing the increase of cancer in Philadelphia during the last thirty years, basing his conclusions on the official reports of death from this disease. Thus in 1861 there were 31.7 deaths from cancer to every 100,000 of the population, an average which has risen

almost constantly until in 1897 the ratio was 56.6 to 100,000. In the former year cancer was the assigned cause of 1.36 per cent. of the deaths, while in the figures for last year it was the assigned cause in over 3 per cent. of all deaths. In England a similar increase has been noted. In 1861 there were only 37.6 deaths from cancer to 100,000 inhabitants, while in 1886 the number had risen to 61.

Massey has had good results in the cure of cancer by the dissemination throughout the growth of the nascent oxychlorid of mercury, or the mixed oxychlorids of zinc and mercury, using a powerful galvanic battery capable of generating a current of 1500 milliamperes for half an hour or more if necessary. Anesthesia is required, and a gold electrode, with a covering of mercury, or an electrode of zinc and mercury is thrust into the growth while large dispersing pads are placed on different parts of the body. Every effort is made to cure the growth at one sitting. Seven patients are reported to have been cured, both carcinoma and sarcoma being included in the list.

Advantages of Nitrous Oxid Mixed with Oxygen for Brief Anesthesia.—GARDNER (*Brit. Med. Jour.*, April 30, 1898) has had such good success from the use of a mixture of nitrous oxid and oxygen for inducing brief periods of anesthesia, twenty minutes or less, that he cannot recommend it too highly. The symptoms accompanying inhalation of nitrous oxid alone are cyanosis, jerky, rapid breathing, twitching of the limbs, and dilated pupils. These objectionable results are avoided by the admixture of oxygen, and a little practice enables the anesthetist to administer the gases in the right proportions. If the breathing grows faster and deeper and the color a trifle dusky, more oxygen is wanted; if quieter and slower, the oxygen must be reduced. At the beginning of the inhalation the patient is given only 2 or 3 per cent. of oxygen, but this amount is gradually increased until 10 or 20 per cent. is reached. The color is normal, the breathing of a softly snoring type, not so stertorous as with ether, not so quiet as under chloroform; the pulse is strong, full, and regular; the abdomen is generally quite flaccid, but the limbs may show a slight tendency to rigidity; though the legs will offer no resistance to being placed in the lithotomy position, they may show slight reflexes from time to time. The blood from an incision during this anesthesia may appear somewhat venous at intervals; this is not, however, due to congestion, but to the fact that nitrous oxid to some extent replaces oxygen in the hemoglobin and the purple color of the new product becomes evident in the flowing blood, even while the facial color is healthy in appearance. Alcoholic patients are not good subjects, nor are very powerful athletic men; but most women and well-nourished persons generally can be regarded as suitable cases, while those who are weakened by illness often take the gases remarkably well.

Frequency of Gall-stones in the Subjects of Mitral Stenosis.—BROCKBANK (*Edinburgh Med. Jour.*, July, 1898) publishes some tables to illustrate the frequency of gall-stones in patients suffering from mitral stenosis. His investigations extended over a period of six years, and the conclusions are based on more than 1300 autopsies. A distinction is made between primary and secondary cholelithiasis. The former occurs in people who are generally over fifty years of age, and otherwise healthy. It is probably due to same nutritional change in the epithelial lining of the biliary passages, so that more cholesterin than usual is secreted, or the solvent power of the bile is decreased. Primary cholelithiasis is rarely met with post-mortem.

In secondary cholelithiasis, the stones are formed at an earlier age in a patient who is suffering from some other complaint, generally of the heart and liver. This condition is fairly common post-mortem, but is rarely suspected during life.

In all, Brockbank found gall-stones in 7.4 per cent. of the autopsies made. They were about four times as frequent in women—15 per cent.—as in men, 4 per cent. Schroeder of Strassburg found them in 4.4 per cent. of male subjects, and in 20.6 per cent. of female subjects.

Gross cardiac lesions seem to double the risk of development of gall-stones in both the male and female, for while in the subjects having normal hearts the percentage of those having gall-stones was 5.4, they were present in 10.9 per cent. of the subjects with imperfect hearts. Of the subjects having mitral stenosis, the proportion with gall-stones was highest of all, or 16 per cent. for males, and 25 per cent. for females, or 21.8 per cent. for both sexes together.

The further interesting fact is reported that the bile in the gall-bladder of many patients who have died from chronic heart disease, but in whom no gross evidence of cholelithiasis is manifest, if examined microscopically, will often be found to be full of desquamated epithelial cells, floating singly or in clumps, together with a few cholesterin crystals. If such bile is examined from day to day it will be seen that the epithelial cells gradually disappear, and that the crystals increase, until the bile contains innumerable numbers of them. Perhaps no better explanation of these phenomena can at present be given than to say that the lowered vitality of the system generally, and the passive congestion of the mucous membrane of the gall-bladder, which accompany severe chronic lesions of the heart, predispose to the formation of an increased amount of cholesterin by the epithelial cells of the biliary passages, and by the enforced inactivity of the patient this excess of crystalline substance tends to remain behind in the dependent fundus of a frequently enlarged, depressed, and sluggish gall-bladder.

Hemiplegia Following the Administration of Chloroform.—INGELRANS (*L'Echo Med. du Nord.*, June 26, 1898) mentions that right-sided hemiplegia developed in a somewhat nervous, but on the whole healthy, woman, upon whom a laparotomy had been performed for uterine fibroids. The operation was not a difficult one, and lasted about an hour. Nothing abnormal was noticed until about four hours later, when it was observed that the right arm and leg of the patient were completely paralyzed, motion and sensation being alike impossible. The face was less affected and she spoke with some difficulty.

Improvement in the symptoms began almost immediately, but for three weeks there was complete incontinence of both bladder and rectum. Sensation returned before motion. Power was first restored in the leg, and more slowly in the arm. Two months after the operation she was able to leave the hospital, although restoration of function was by no means complete. There was a suspicion of syphilis in the case, but the patient, although a widow, had never miscarried nor borne children. Iodid of potash was given from the time of the attack.

Ingelrans was able to collect from medical literature fourteen cases in which a paralysis, either motor or motor and sensory, followed the administration of chloroform. This accident was variously explained by the different operators. In one case it was ascribed to hysteria; in another to an old apoplectic attack. At autopsy in one case there was found a fresh hemorrhage in the brain, in another an area of cerebral softening without obvious cause, and in a third a serous effusion into one of the ventricles. Besides the advocates of the theories of cerebral hemorrhage and cerebral anemia with necrosis, to explain the paralysis, there is also those who say that chloroform has a direct toxic action on the cells of the body, and they cite the presence of albumin in the urine after chloroform as a proof of this. There is wanting, however, the clinical evidence to support this explanation of the paralysis.

The prognosis of this complication of anesthesia is good. Three of the patients whose cases have been reported died in a short time, but none of them from the effects of the paralysis. One died from a bronchopneumonia, one from the cancer which was the cause of the operation, and one from the sequelæ of his strangulated hernia. In all the other cases the paralysis either disappeared entirely, or was greatly improved at the time the report was made.

THERAPEUTIC NOTES.

The Cure of Writer's Cramp.—MONELL (*Med. Record*, July 23, 1898) makes some pertinent remarks about the so-called neuroses, "writer's" or "telegrapher's cramp." These troubles are not really neuroses, but are the result of malnutrition. After exercise a muscle repairs its wasted fibers during a period of rest. When the use has been so violent or so long-continued that this repair cannot take place there is a permanent impairment of the muscle. It cannot be restored to its normal condition by rest. Were this possible almost all of the severe cases of telegrapher's cramp would be unknown, for all of these patients give a history of periods of rest in the attempt to regain lost power. The fact that the cramp occurs is only another way of saying that the muscles have lost the power of repair through rest. Hence it is worse than useless to tell these patients to rest.

Massage is successful in a certain number of cases in restoring the patient's muscles to their previous condition, but it is at best a clumsy way of accomplishing this end, and in the severer cases it fails of its purpose. The nutrition can, however, be restored by the persistent use of galvanic and static electricity. The plan of treatment advocated is to give the muscles first a gentle warming-up application to quicken the circulation, as the preliminary canter warms up a racehorse before he enters the race. The arm is next subjected to general nutritional muscular contractions, regulated in energy and number by the tolerance of the tissues. Finally the arm is given a refreshing, restful, nutritional application, which leaves it at the close of treatment invigorated, buoyant, and elastic. The total treatment requires about ten minutes, and every moment and every detail of each application aims at improving the nutrition of muscle-fibers. In all cases, even the most severe, such treatment will give in a week's time a feeling of comfort, and in the lighter cases there will be in two weeks a complete cure so that the patient may return to his work. In severer cases treatment must be longer continued, but no case is so severe or so long standing that it may not be fully cured in from forty to sixty treatments. General treatment of the health is naturally attended to, and in every case the local improvement will continue long after the treatment has been suspended. In the more severe cases it is desirable that the patients come back every year for a fortnight's treatment. The value of this treatment in improving the nutrition of the muscles is also shown by the fact that there is no operator of long experience, no matter how fine he may think his arm, but can be improved twenty-five per cent. in speed and ease of operating by a dozen treatments. For the details of this method of treatment the reader is referred to the author's "Manual of the Use of Static Electricity in X-Ray and Therapeutic Uses."

Recovery from a Large Dose of Strychnin.—LEFFINGWELL (*Phila. Med. Jour.*, July 23, 1898) reports his successful treatment of a patient who had swallowed 10 grains of strychnin with suicidal intent. The period of time that elapsed between the taking of the poison at the beginning of the treatment could not be learned. The whites of eight eggs were given, and immediately afterward a large teaspoonful of mustard in a glass of water. This was followed up until the stomach had repeatedly emptied itself.

During this time three clonic spasms occurred, affecting the lower jaw, the upper extremities and anterior muscles of the trunk of the body, the lower extremities being wide apart and motionless. Sudden noises or voices, and only slight contact with any one around the patient, without his permission, would excite another attack; and the number of these during the eleven hours he was under treatment was about forty, lasting from ten to thirty seconds each.

Ice-water was given for the great thirst, and the patient was then allowed to inhale ether to control the convulsions. Bromid of potash was given in 20-grain doses at intervals of every half hour, and then of every two hours until 140 grains had been taken. Morphin sulphate was injected subcutaneously, ¼ of a grain every two hours, until the pain in the lower extremities was relieved and the threatened asphyxia passed over. After twelve hours of treatment it became evident that the man would recover, as the pains were much less, and he was able to draw up his lower extremities.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

"THIS ARMY MUST BE MOVED AT ONCE OR PERISH."

SUCH is the startling announcement that came from the officers of the victorious army after the surrender of Santiago and finally aroused the authorities at Washington from their lethargic indifference to the fate of those gallant men. It came in response to an order to move the camps up into the hills where the exhausted and disease-stricken soldiers could be made as comfortable as the tropical rains and torrid sun and miasmatic climate would permit; while the transports which might be used in bringing them home were preparing to carry out to Porto Rico the politicians' friends for a holiday tramp across that innocent island. Almost simultaneously came the telegram from General Miles, "Do not send me any more troops," and the remonstrance of the Round Robin from General Shafter's officers, "This army must be moved at once or perish."

What more startling rebuke could be given to departmental incompetency, or what handwriting on the wall could say with more distinctness, "Thou hast been weighed in the balance and found wanting?" It is a fitting climax to the incompetency that landed the army in Cuba and abandoned it to its fate devoid of necessary medical and surgical supplies and the commonest commissary stores, and yet no one was responsible! Most glowing accounts appeared of the up-to-date preparations for caring for the sick and wounded—improved ambulance and hospital facilities, ingeniously compact delicacies for the sick, etc., and yet when the demand for them came almost nothing was at hand—a complete breakdown of the service, and no one responsible! Thousands of brave men who have done their duty valiantly in the face of the enemy incapacitated for want of proper food and shelter, and hundreds dying because of insufficient transportation and hospital facilities, and no one reponsible! Every National Volunteer camp in the country seriously afflicted with typhoid fever, and no one responsible!

Such shocking, such mortifying spectacles as the "Breakwater," the "Seneca," and the "Concho," aggravated later by the "Santiago," the "Comal," and the "San Marcos," bowing the richest, the most resourceful nation in the world in shame, and no one responsible! A large proportion of the suffering endured and death sustained by our soldiers, admitted on all sides as avoidable and hence, unnecessary, and yet no one responsible! A universal demand for an investigation and the fixing of the responsibility, and yet no investigation ordered! But come it will.

As Columbia says to Uncle Sam, "The *Government* must fix the responsibility or the Country will."

HOSPITAL REPORTS.

THE example set by three large hospitals of this country—the Johns Hopkins of Baltimore, the Massachusetts General of Boston, and the Presbyterian of New York, should have, as we believe it will, a larger immediate following. The presentation in well-printed form of unusual, interesting, or even of a series of ordinary cases, occurring in hospital services, fulfils a didactic purpose of no mean value. We are all too familiar with the hackneyed hospital report. It is a carefully compiled statement of how many pounds of candy Mrs. X. has sent to the children's ward, of how many religious journals have been donated to consume the time of convalescent patients, and of how many pillow-cases and nightgowns the Young Woman's Auxiliary Society has

given. It runs over with praise of every one connected with the institution from the governing board to the orderlies, while the medical and surgical work of the year is condensed into a few statistical pages.

We assume that such printed rubbish is essential to the well-being of hospitals, else the custom of giving it annual birth would long ago have ceased. Governing boards are learning, however, that every hospital is obliged to fill certain didactic functions, and when clinical teaching cannot be directly given, the publication by the medical board of reports such as that the Presbyterian Hospital recently issued, in part assumes this function, though somewhat vicariously.

The educational worth to the hospital interne of accurate record-making and the careful taking of histories, essential to a published report of cases, is important, too. It draws him away from hackneyed lines, it sharpens his powers of observation, and augments the value of his clinical experience in proportion to his native ability and the watchfulness of his superiors. Nor is the literary value of such efforts to be despised, a consideration for the future usefulness of internes trained to observe, to write, to teach.

The variety of subjects covered can be duplicated, we do not doubt, by any metropolitan hospital and by many such institutions, indeed, in smaller towns. Since the aggregate fund of hospital experience forms the basis of most teaching and of most medical knowledge, medical boards should feel it incumbent upon themselves to assist in the diffusion of medical learning by the systematic publication of the real medical and surgical work in their respective hospitals. We are far behind England, France, and Germany in this respect. Perhaps with our now advanced position among the nations of the world, we will improve in the matter of hospital reports, too.

THE TONSILS AS CHANNELS OF INFECTION IN TUBERCULOSIS.

A FEW years ago Dr. G. Sims Woodhead, in a very thoughtful and scholarly address, suggested, and in a measure proved, that tuberculous infection of the glands of the neck occurs frequently through the tonsils, especially in children living under unsanitary conditions and subject to various devitalizing influences. His investigations tended to show that the rôle played by the tonsil and the surrounding lymphoid tissue in antagonizing infection when its tissues are normal, and in facilitating infection when diseased, is more important than usually considered. Recently Dr. Hugh Walsham of London has busied himself with the same subject, and the results of his studies are embodied in an article in a recent issue of the *Lancet*. He made a careful examination of the tonsils and follicular glands at the base of the tongue of every subject of tuberculosis which came before him for post-mortem examination at the City of London Hospital, and he also examined a large number of tonsils and adenoid vegetations that had been removed by surgical operation.

In the vast majority of post-mortem cases there was no symptom during the life of the patient to call attention to the tonsils. Despite this, in twenty out of thirty-four subjects examined these glands were found to be tuberculous. The results of his examination of tonsils and adenoid tissue removed from living patients were entirely negative, as in no one was indications of tuberculosis found. Walsham believes that the view of so many pathologists and clinicians that the tonsils are almost immune from tuberculous disease, is absolutely untenable, and that these glands are very often affected. Whether the tubercle is often primary of the tonsil, as was suggested by Woodhead, cannot be determined with any degree of positiveness, for although it is sometimes primary, the tonsils are very frequently affected secondarily in persons suffering from pulmonary tuberculosis. Concerning the way in which the tonsils become affected, he believes that it may be from without, or in acute miliary tuberculosis through the blood stream. When the tonsils are tuberculous the cervical glands receiving the lymphatics from these organs are frequently affected with tubercle, but the follicular glands at the base of the tongue are rarely implicated.

One practical application of these studies seems very apparent, and that is, that disease of the tonsil, even though slight and apparently insignificant, may open up a highway to tuberculous infection which would otherwise be impregnable, for it is highly improbable that the bacilli penetrate the normal intact

epithelium lining the tonsillar crypts. It would be interesting to know, now that the tonsils have been shown to be channels of infection in tuberculosis, if statistics show that persons who have had partial or complete tonsillotomy are more susceptible, or less so, to cervical and intrathoracic tuberculosis.

ECHOES AND NEWS.

The Will of Dr. Pepper.—Dr. William Pepper left no public bequests. His will provided for a gift of $75,000 to the University of Pennsylvania, but a recent codicil revoked it.

Effects of Sanitation at Santiago.—The sanitary precautions taken since the occupation of Santiago by the United States forces, according to the latest reports, have reduced the average daily death-rate from 103 to 37.

A Cheering Cargo for the Invalids at Santiago.— The Auxiliary Cruiser "Yale" left New York recently for Santiago with a large quantity of commissary stores, including medical stores and delicacies. Among the latter were 1000 bottles of champagne, 5000 bottles of ginger-ale, 200 cans of malted milk, and 1000 cans of beef extract.

Michigan State Board of Health.—Dr. Arthur B. Reynolds, Health Commissioner of Chicago, in an address recently delivered at Detroit, said "It is not too much to say that the State Board of Health of Michigan has, in the language of our great classic in hygiene, Edmund Parkes, made growth more perfect, decay less rapid, life more vigorous, death more remote, for every citizen within the boundaries of this fair State."

A Bullet Successfully Removed from the Spinal Column.— Dr. F. D. Bird of Melbourne, Australia, gives an account in the *Inter-Colonial Medical Journal* of a patient treated by him for gunshot injury near the angle of the jaw. After the flesh wounds had healed, some cervical pain and stiffness of the neck on the left side were felt. A skiagram of the neck was taken revealing a foreign substance in the body of the axis. This proved to be a bullet, which was removed, the patient making a complete recovery.

New York Post-Graduate Medical School.— The seventeenth annual announcement of the New York Post-Graduate Medical School and Hospital, University of the State of New York, for 1898–99 has just been issued. It records 523 practitioners of medicine as in attendance upon its courses during the past year. They came from the various States of the Union and the Dominion of Canada. There were ten physicians from foreign countries, two of these being from India and one from Japan. Only 96 were from the State of New York.

Health of the Eighth Massachusetts Regiment.—Colonel Pew of the Eighth Massachusetts Regiment, stationed near Santiago, reports that his is the healthiest regiment in Cuba. It would be interesting to know what particular circumstances have brought about this condition. Have the soldiers of Col. Pew's command had less intercourse with the refugees than the men of other regiments? Have they had less experience in the trenches? Where have they been encamped; on the hills or near the coast?

The Physical Condition of Capt. Clark of the "Oregon".—Captain Charles E. Clark, commander of the battleship "Oregon," upon the report of the Board of Medical Survey, has been relieved of his command and granted a leave of absence. Captain Clark has broken down physically under the terrific strain to which he has been subjected during the last four months. The wonderful record made by the "Oregon" on that 15,000-mile voyage is generally conceded to be due to the efficiency of Captain Clark, although Chief Engineer Millikan is entitled to some of the credit.

Yellow Fever in Louisiana.—A fatal case of yellow fever was reported August 12th at Franklin, La. The Louisiana State Board of Health has quarantined the entire parish of St. Mary, and forbidden all railroad trains stopping there. The States of Texas and Mississippi have both quarantined against the parish. Surgeon-General Wyman promptly sent two Marine Hospital surgeons to investigate the report, remain on watch, and quarantine all suspicious cases. The reported case is supposed to have originated from the tearing down of a shed which became infected last year. The shed should have been destroyed by fire. If such is the history of the case no difficulty should be experienced in preventing any spread of the disease.

Chronograph Watches for Nurses.—The latest edition to the equipment of the trained nurse is a chronograph watch. These watches are especially made to enable trained nurses to accurately take the pulse of their patients. The moment the pulse has been taken, the large second hand can be instantly stopped by a slight pressure upon the stem of the watch. If there has been any uncertainty or fluctuation in the pulse, the second hand can be quickly thrown back to the starting point and the pulse re-taken without in any way interfering with the other mechanism of the watch. It is said that the first timing watch was made about fifty years ago and was called the "surgeon's pulse," which indicates that one of the present uses of the watch by physicians and nurses is really going back to first principles.

Immune Regiments for Santiago.—The fact that a number of men, who had survived an attack of yellow fever, enlisted and went to the front with the full assurance that they could face the dread disease with impunity, have been attacked with yellow fever, and some of them even died from it, has put a new phase upon the significance of the word immune. It is quite possible that life in a Northern climate so renovates the system after an attack of yellow fever as to interfere with the proper balance between the toxins and antitoxins, and so destroys the security against a second attack. If this

proves to be the case, it will be necessary to secure an immune army from the ranks of men who have continued to live in a tropical or semi-tropical climate after the first yellow-fever attack.

Compulsory Vaccination in England.—As a result of the recent epidemic of smallpox, which brought such distress upon the inhabitants of Gloucester, a bill making vaccination compulsory was introduced in the English Parliament. It was generally understood that the Government party was united and determined in its decision to pass the bill, but suddenly some move on the political checkerboard changed the whole aspect of the question, and an amendment was passed by the House of Commons which rendered the compulsory clause nugatory. This clause provides that "no parent or other person shall be liable to any penalty for violating the law, provided he satisfies two Justices in Petty Sessions that he conscientiously believes that vaccination would be prejudicial to the health of the child." This unexpected change of front on the part of the leaders of the Government party is thought to have been due to the Reading election which was going on at the time. The anti-vaccination party is strong in Reading; it is an important town, and the Government was anxious to retain the seat. Our sympathy goes out to the profession of England in its dilemma. We, on this side of the water, have had occasion to bemoan similar miscarriage in legislative sanitary measures and for similar reasons.

Personal Characteristics of the Late Dr. William Pepper.—It is said of Dr. Pepper that he rarely spent as much as six hours nightly in bed, and took the balance of his sleep as he needed it throughout the day. Short naps were his only relaxation, and sleep was to him as wine and was taken as readily. "Will you excuse me, Mrs. ———," he would say sometimes, "I could talk with you much more satisfactorily if I had a few minutes' nap. Nurse, make Mrs.——— comfortable and wake me in ten minutes." Ten minutes later, he would be aroused by the nurse and at once resume his conversation with the patient at the point at which he had dropped it. He would sleep in his carriage as he was driven from one appointment to another; he would sleep in the train, in a strange parlor or library, in private or public, absolutely indifferent to comment. "I have already seen the patient, gentlemen," he sometimes said to consultants, "I will not go in with you; just wake me when you have finished your examination." Dr. Pepper's brain was always at work. His valet and stenographer awoke him at 6.30 A.M., and he began hearing letters and dictating answers at once, his valet, meantime, dressing him. He dictated from his bath, while he was being dressed, at his breakfast, and sometimes for an hour afterward. In his consultation work, special railway trains were the familiar time-saving devices, and his familiarity and influence with railroad presidents enabled him to order them as he would cabs. Dr. Pepper was one of the most tactful men in dealing with patients. He sometimes kept three or four patients "in the air" at once, all sitting in his inner office, and each, under the power of his tact, as well satisfied as if he were given a private hearing.—*New York Herald.*

Quarantine Regulations for Cuban and Porto Rican Ports.—To expedite the movement of the transports bringing soldiers from Cuba and Porto Rico and to minimize the danger of their exposure to infection, Marine Hospital surgeons have been detailed for duty at Santiago and Ponce to enforce the quarantine laws, to issue certificates, and to perform other duties of sanitary or port inspectors. The system will be extended to other Cuban and Porto Rican ports as fast as they are acquired by the United States forces. At Santiago and every chief port where practicable, a receiving ship will be stationed for the reception of those who take passage for ports in the United States. This ship will be practically a detention camp and quarantine station, and passengers seeking homeward voyage are to be taken from the receiving ship after they have undergone a period of observation and disinfection of baggage. This precaution, together with the placing of a Marine Hospital surgeon in charge of every transport bringing soldiers from the front, will render unnecessary such vexatious delays in quarantine as have recently been imposed on the vessels conveying wounded and convalescent men to the United States, as the disinfection of the transports will not then be required. Secretary Alger has issued the following order on the subject: "All sanitary matters pertaining to the condition of transports and crews are to be placed under the jurisdiction of the medical officers of the United States Marine Hospital Service. Every vessel engaged in the transport service between the United States and Cuban or Porto Rican ports is to carry a medical officer of the army or of the Marine Hospital Service, whose duty shall be that of sanitary inspector of the vessel, and who shall see that in a foreign port no material or person is taken aboard liable to convey yellow fever; to keep the crews of the transports under surveillance, and on the return voyage act as sanitary inspector."

Duties of Marine Hospital Surgeons on Transports.—Surgeon-General Wyman of the Marine Hospital Service has issued the following instructions for the guidance of Marine Hospital surgeons detailed for duty on army transports: "Your duties are primarily to keep the transports from becoming infected. At the foreign port the crews must be forbidden and prevented from going ashore; everything brought on board from shore must be inspected, and, if doubt exists, rejected or disinfected. All persons coming on board at foreign ports must be inspected at the gangway. Vessels must lie off the shore and not go to dock. Certificates from medical officers of the Marine Hospital Service on duty at Santiago and other ports should be accepted. If troops are brought on board, obtain certificate from responsible medical officer of the army of freedom from infection. No passengers should be allowed on board except on written order of the commanding general (see correspondence on this subject with War Department, copy herewith inclosed). If a transport brings back sick or wounded soldiers the latter are under the care of the medical officer of the army detailed for this

purpose. For their treatment, medical supplies, etc., the Medical Department, United States Army, is responsible. The crews of the vessels, however, are under your professional care, and a supply of drugs, etc., has been sent you for this purpose. If, however, you are called on by the proper authority for assistance of the sick or wounded soldiers, you are authorized to render it. In absence of a regular medical officer of the army you will, of course, render such assistance as the ordinary dictates of humanity demand. Look carefully after water-supply. Keep accurate notes and furnish such certificate as you are able to give to the quarantine officers at the port of arrival in the United States. Transmit reports to bureau on arrival in home port. At Santiago and other ports you will communicate with the medical officer of the Marine Hospital Service in command, and will receive and obey any reasonable order from him. Disinfectants will be furnished from the bureau on requisition as soon as practicable, but if for any reason purchase is necessary, the officer may purchase in accordance with the regulations of the Marine Hospital Service. These instructions will be amended or added to hereafter, and if for any cause it is impracticable or impossible to enforce them, the officer must carry out their spirit, if not their letter, to the best of his ability, and then report the facts to the bureau." The medical officers on duty on the army transports have been furnished with necessary outfits, and to those at Santiago steam chambers, boilers, sulphur furnaces, generators, and a large quantity of disinfecting material have been forwarded.

New York State Medical Association.—The regular annual meeting of the New York State Medical Association will be held at 64 Madison avenue, New York City, on October 18, 19, and 20, 1898. The following is the preliminary program: "A Practical Demonstration in the Reduction of Infantile Mortality," by Dr. E. F. Brush of Mount Vernon; "The Pneumogastric Nerve in the Production of Stomach Disease," by Dr. Julius Pohlman of Buffalo; "The Coccyx," by Dr. J. E. Walker of Hornellsville; "Drugs *versus* Cardiac Insufficiency," by Dr. O. T. Osborne of New Haven; "The Passing of Alcohol," by Dr. J. M. Farrington of Binghamton; "A New Method of Amputation at the Knee-joint Applicable in Cases of Senile Gangrene of the Foot," by Dr. Stephen Smith of New York; "Anthropological Rambles in the Orient, Especially in the Island of Java; Profusely Illustrated with Stereopticon Views," by Dr. H. Ernst Schmid of White Plains; "Dental Pathology in Its Relationship to General Health," by Dr. Dwight L. Hubbard of New York; "Subnormal Temperature," by Dr. Leroy J. Brooks of Norwich; "Ancient and Modern Animal Products Used as Medicines," by Dr. T. J. Acker of Croton-on-Hudson; "The Treatment of Cases of Pulmonary Tuberculosis That Cannot Go Away from Home," by Dr. Delancey Rochester of Buffalo; "Some Observations of General Interest Regarding the Course and Management of Cataract," by Dr. J. H. Woodward of New York; "Technic and Use of Saline Infusion," by Dr. Thomas F. Reilly of New York; "What to Do to Be Saved, Being the Conclusion of the Inquiry into the Abuse of Medical Charity," by Dr. Thomas J. Hillis of New York; "True and False Medical and Other Charities," by Dr. Wickes Washburn of New York; a paper by Dr. Charles Phelps of New York, title not yet announced; "Genital Neuralgia and the Genito-reflex Pains," by Dr. F. P. Hammond of New York; "Lantern-Slide Exhibition," by Dr. S. Alexander of New York; "A Case of Attempted Obliteration of the Deformity in Pott's Disease," by Dr. Charles Allen Tuttle of New Haven; "Notes on Neuralgic Affections of the Head," by Dr. Gustavus Eliot of New Haven; "The Use of Catgut Sutures in Ventrofixation of the Uterus," by Dr. J. E. Janvrin of New York; "Traumatic Tetanus—Report of a Case Following an Attempted Operation, Treatment, etc.," by Dr. Z. J. Lusk of Warsaw; "Some Thoughts on Rational Treatment of Disease," by Dr. Chauncy P. Biggs of Ithaca; "Senility," by Dr. F. W. Higgins of Cortland; "A Case of Extra-uterine Pregnancy Operated upon at Term," by Dr. Eli Van deWarker of Syracuse; "Memoranda," by Dr. H. D. Didama of Syracuse; "Diagnosis and Surgical Treatment of Renal Calculus," by Dr. N. Jacobson of Syracuse; "Eye Lesions in Some Diseases of the Kidney," by Dr. H. S. Oppenheimer of New York; "Insanity Following Surgical Operations," by Dr. W. D. Granger of Bronxville; "Dermoid Cysts of the Ovary," by Dr. C. E. Fritts of Hudson; "The Operative Cure of Inguinal Hernia in Men," by Dr. E. D. Ferguson of Troy; "Urethral Stricture," by Dr. J. W. S. Gouley of New York. A discussion on intestinal obstruction comprising the following papers: "Introduction," by Dr. Parker Syms of New York; "The Causes of Acute Intestinal Obstruction, with the Description of Their Mechanism," by Dr. E. D. Ferguson; "The Causes of Chronic Intestinal Obstruction, with a Description of Their Mechanism," by Dr. J. D. Bryant of New York; "Intestinal Obstruction Due to Impaction of Feces, Gall-stones, Foreign Bodies, etc.," by Dr. J. W. S. Gouley; "The Diagnosis and Indications for Treatment of Acute Intestinal Obstruction," by Dr. J. D. Rushmore of Brooklyn; "The Diagnosis and Indications for Treatment of Chronic Intestinal Obstruction," by Dr. Leroy J. Brooks; "Intestinal Obstruction Due to Intussusception and Volvulus," by Dr. John F. Erdmann of New York; and "The Technic of Operative Treatment of Intestinal Obstruction," by Dr. Frederick Holme Wiggin of New York.

CORRESPONDENCE.

MUCOUS-MEMBRANE ERUPTION IN MEASLES.

To the Editor of the MEDICAL NEWS.

DEAR SIR: I read in your issue of June 25th, on page 818, an article called "Koplik's New Sign of Measles," and, also, Dr. A. L. Hall's comment thereon in the MEDICAL NEWS of the 23d ult., on page 122, with considerable interest. I am fully in accord with Dr. Hall's observations with regard to the sign not being very new for I have made use of it in almost all of my cases during the past eight years. I do not recall ever having seen it

mentioned in print before, but because of its great frequency I have no doubt that many physicians have observed and recognized its value.

I have a record of one case where this sign was present forty-eight hours before the skin eruption appeared and because of it I made a positive diagnosis of measles. I consider it the very earliest absolute sign of measles.

This difference from Slawyk's report I must make: I find the eruption located first on the mucous membrane about the junction of the soft with the hard palate on the roof of the mouth. I have observed it at this point when nowhere else, and in about ninety per cent. of all my cases. The average time of its appearance before the skin eruption was about twelve hours.

Respectfully,

EMMERT C. STUART, M.D.

PITTSBURG, PA., August 15, 1898.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

CERTAIN FORMS OF SORE FEET IN SOLDIERS AND RECENT REPORTS OF GERMAN MILITARY SURGEONS —NO FOREIGN SCIENTISTS PERMITTED AT THE CONGRESS OF POLISH NATURALISTS AND DOCTORS —A CASE OF GIGANTISM IN A CHILD AGED FOUR YEARS—TUBERCLE BACILLI AND THE PRODUCTION OF HEART LESIONS.

BERLIN, August 9, 1898.

A RECENT number of the *Deutsche Medicinische Wochenschrift* reviews three articles that have appeared within the last year on that indefinite condition swelled foot or edema of the feet, that so often occurs in people, like soldiers, who are much on their feet and have in addition suffered from slight accidents. The articles are all from military medical men who have made special studies of the subject and of late have called the Röntgen-rays to their aid in the matter. One of the articles I called attention to some time ago in this column, but circumstances seem to invite more special attention to it just now. All three of these surgeons have found that these foot conditions which are apt to be set down simply as sprains, and really make up the vast majority of the cases that are entered in case-books under the indefinite head of sprained ankle, are really due to fractures of the metatarsal bones. In certain cases the line of fracture can be distinctly seen in the Röntgen photographs, though in many it cannot. In some even after the healing the callus is visible in the same way. Kirchner reports fifty-five cases of the condition in all of which some characteristic symptoms of fracture could be demonstrated when it was carefully looked for. He considers that in all of these cases in which, after slight injury, a turn on the foot, a misstep, sometimes the failure to notice a step, or the like, edema of the foot develops, with tenderness when the foot is used, the underlying pathological condition is a metatarsal fracture. The treatment is, of course, rest and then firm support that practically immobilizes the metatarsal joints afterward. He warns especially against meddlesome massage and attempts to reduce the swelling in the early stages and overcome the stiffness that is Nature's protective mechanism, during the progress of the cure, by manipulations of the foot. Such misdirected efforts lead to the development of that chronic soreness so often seen as a sequel in these cases, and which may persist as a torture to the patient for the remainder of life.

The German government has evidently taken to heart the lesson furnished by the results of the *laisser-aller* policy of the Austrian government in the matter of Slavish agitation. The eighth annual meeting of the Polish Naturalists and Doctors was to have been held at Posen in the German province of the same name, from the 1st to 4th of August. It was announced that a number of Czechish and Russian scientists and medical men were to be present and there was an evident purpose to rival by anticipation the German Congress of Naturalists and Physicians to be held at Dusseldorf the beginning of September. Recent events in Austria and the tone of certain Polish, and especially Czechish journals, seemed to indicate that the occasion was to be made use of as a sort of love-feast for the Slavs—a family reunion of the branches of the race, at least as regards its scientific and medical men.

Any such purpose the German government of course considers as liable to be subversive of the peace that has always reigned in the Eastern German provinces between the Germans and Slavs, despite the considerable number of the latter that are there. They had before their eyes the warning example of a Slavish Congress held in Prague some months ago, in which the Russian representative, a little flushed with generous wine perhaps, stated in no dubious terms the purpose of the Slavs to have their revenge for their centuries of subjection to German sway. The attendance of foreign scientists and medical men at the Congress at Posen was, therefore, officially forbidden by the police president of the Province. The Committee of Arrangements of the meeting protested against this decree. They pointed to the fact that the Congress had been held in Posen some years ago, and, without any such uncalled for regulation, had simply and faithfully devoted its time to the scientific purposes for which it meets and that there had been no political agitation. The protest did not avail, however, despite the fact that the committee pointed out that invitations had been already sent to certain foreign scientists and accepted by them, there having been no question in the mind of the committee of possible discourteous interference on the part of the police in a purely scientific matter. The police president reasserted his belief in the purpose of the meeting to serve certain political ends and refused to lift the ban against foreigners. As a result, the Congress was not held at all. So closes for the moment another phase of *the* question of Central and Eastern Europe, the Slavish and German. It crops up now in every relation between the two people, political, linguistic, social, commercial, and has even invaded science. The new-born race self-consciousness of the Slavs, which is drawing together these people in Central Europe, makes a most interesting phase of later ethnology, elements that were supposed to be (that have been in the past) infinitely repellent, have under the subtle magic of this new force somehow changed what was considered their inherent polarity and exhibited at-

traction instead of repulsion. The Poles and the Russians were supposed to be inveterates irreconcilable enemies. The Czechs were a despised branch of the family, for whom the other two had no consideration, though the keynote of their relations with them would undoubtedly have been opposition had they considered it worth the while to have any relation. Now these are the three who sit down at the council board together to discuss German decadence and Slavish advance.

Meantime, if what seems a natural force is to be retarded in its progress, this immediate interference of the German police at the first suspicion of the introduction of the Slav agitation into the German empire will have its effect. Natural forces have, however, a way of surmounting artificial barriers that is not always complimentary to self-conscious human acuity. Mrs. Partington was once quoted in the British Parliament as having been an excellent hand with a mop, but when the Atlantic Ocean kept coming in under the door-sill her cunning with that very useful remover of nuisances did not avail much. One is tempted to wonder whether even a paternal German government, in which imperialism is the watchword, will be more effective against this natural force that has been gathering strength in the obscurity of centuries and now presents one of the most interesting natural phenomena at work in our own time that history has ever presented.

Dr. Michaelis, Professor Von Leyden's assistant, who has been able to demonstrate the gonococcus several times on the heart valves in gonorrheal endocarditis, found some time ago tubercle bacilli in cardiac vegetations in certain cases of tuberculosis, either acute or with the acute exacerbations indicating that at some time the bacillus was in the circulation. The question arose whether the bacilli were only coincidently present in the vegetations, as a consequence of their presence in the blood current at a moment when their imprisonment was favored by some concomitant diseased condition of the valves, or whether they really played an etiological rôle in the production of the vegetations.

Working under Dr. Michaelis' direction in Professor Von Leyden's laboratory, Dr. Blum of San Francisco has been able to demonstrate, experimentally, that the tubercle bacilli are an active factor in the production of the valvular vegetations, and Dr. Michaelis reported the observations and demonstrated the specimens at the last meeting of the Verein für Innere Medicin. The aortic valves in rabbits were injured by the insertion of an instrument through the carotid and then tubercle bacilli were injected into the circulation. When the animals were killed some weeks later, in certain cases vegetations were found on the valves at the injured parts, in which a pure culture of tubercle bacilli could be demonstrated. The experiments are taken to prove that valvular lesions may be the result solely of tuberculous infection, a question which has hitherto been in dispute.

An interesting case of gigantism in a child of four was presented before the Association of Attendant and Resident Physicians of the Charité Hospital (Charité Arzte), Berlin, at a recent meeting. The child has the stature and the weight of a child of seven or eight years. Between the first and second year, after a normal development, there occurred a series of epileptiform seizures. After a time these remitted and the child became seemingly healthy. Then about a year ago it became irritable, afterward subsiding into a state of lethargy for a time. Since then the abnormal development has taken place. This affected all parts about equally so that the child looks symmetrically developed but is about twice its normal size. The penis and scrotum is particularly developed and constitute the only appearance there is of acromegaly. There are symptoms present of a tumor at the base of the brain, choked disk, eye muscles palsied, etc., and it is concluded that there is a neoplasm in the hypophysis. The question that came up for discussion was whether this should be considered a preliminary stage of acromegaly. Many reports of cases of gigantism in children shows that typical acromegaly has developed after puberty, and it is generally considered that the two are analogous processes at least. Professor Heubner and Professor Gerhardt were undecided in the matter.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

Sixty-sixth Annual Meeting, Held at Edinburgh, July 26, 27, 28, and 29, 1898.

(Specially reported for the MEDICAL NEWS.)

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

(Continued from page 223.)

THIRD DAY—JULY 29TH.

DR. R. C. BUIST of Dunblane read a paper, reporting

TWO SYMPHYSIOTOMIES.

In the first case the woman's first child had died in labor; the second labor was a difficult forceps case and the child died; in her third pregnancy labor was induced at 7½ months and the child lived sixteen hours; in her fourth pregnancy the author adopted Franck's method of permanently enlarging the pelvis. Labor set in prematurely a week after the operation, and after twelve hours she was delivered with forceps. The child only lived about two weeks, but the pelvis permanently healed with greatly increased dimensions.

The second patient was not seen until she had been in labor two full days. The os was dilated to about the size of the palm, but the head was fixed at the brim of the pelvis. Under chloroform, symphysiotomy was performed by the subcutaneous method, the forceps applied, and the child easily delivered. The child weighed 8½ pounds, and is now alive and well. In less than three months the mother was at work in a jute mill. The symphysis is still freely movable.

DR. AMAND ROUTH of London read a paper on

TREATMENT OF CYSTOCELE.

Cystocele may be primary or secondary; secondary in procidentia and prolapse of the uterus, and primary when, in labor, the anterior vaginal wall is stretched and the bladder is not drawn up out of the way, and more com-

monly when the membranes have ruptured before the cervix is fully dilated. Treatment by pessaries is usually first tried, but if the cystocele is primary they do little good. The writer then spoke of an operation which he had found useful; the cervix is drawn down and a transverse incision made; then the bladder is stripped off from the front of the uterus and anterior vaginal wall; a vertical incision is made toward the urethra, and the side flaps are allowed to overlap; then the redundant tissue is cut off, some from in front of the transverse incision and some from the sides; two points from the sides are brought down by sutures and sutures passed in both directions so that the vaginal wall is shortened laterally and anteroposteriorly.

PROFESSOR SANGER of Leipizg said that he makes a median incision and then cuts off the side flaps and closes with a continuous suture. He does not think that an anterior operation is enough, for there is always a tear in the perineum which must be repaired.

DR. SMYLY of Dublin read a paper on

EXTIRPATION OF MYOMATOUS UTERI BY THE VAGINA.

He mentioned some of the indications for operation on myomata, such as pressure upon some organ, especially the bladder or uterus; rapid enlargement, especially in a young woman; suppuration, sloughing, edema, pain, hemorrhage, and cases in which the woman is incapacitated from earning her living. He gave the following reasons why the vaginal method is preferable to the abdominal in suitable cases: the mortality is less, shock is less marked, convalescence is more rapid, and there is no abdominal wound. He had performed the operation seventeen times with only one death, and in that case the myoma had suppurated, but the condition was not suspected until the growth was cut into and the putrid matter escaped; the patient died of septicemia. He used Dr. Doyen's method of morcellation, and thought it a good operation for that class of cases in which the adnexa were to be removed. The nervous symptoms of the patient are less severe after removal of the uterus and ovaries than after removal of the ovaries alone.

DR. J. FARRER of Gainsborough read a paper on

A NEW AND SPEEDY METHOD OF DILATING A RIGID OS IN PARTURITION.

He told how he had discovered the method while attending a primipara. For forty-eight hours the os had been thin, rigid, and unyielding; he had attempted to dilate it with his fingers and with a mechanical dilator, with and without chloroform, but had failed. At last he decided to incise the os, and, the patient being too much exhausted to stand chloroform, he applied a ten-per-cent. solution of cocain to the os as a local anesthetic; at the end of four minutes he found the os fully dilated and as soft and flexible as a rubber band. Thinking that the cocain was the cause of the relaxation, he had tried it several times since, always with the same results.

DR. JARDINE of Glasgow said that he had tried this method several times, using 2-grain cocain suppositories, but had always failed.

DR. A. DONALD then read a paper on

VAGINAL SECTION.

He said he employed the term "vaginal section" to imply the opening of the abdominal cavity, or gaining access to the organs therein, through the vagina. During the last six years he had performed this operation fifty-nine times for exploratory purposes, treatment of pelvic abscess, ectopic pregnancy, and myomectomy and ovariotomy. In thirty cases the incision had been anterior and in twenty-nine it had been posterior. The points in its favor are: absence of shock, less risk of septic peritonitis, less likelihood of getting pus into the peritoneal cavity, and a quicker recovery and better convalescence. In cases in which the uterus is fixed by adhesions and there is a long, narrow vagina it is better not to attempt vaginal section. His mortality had been six per cent., and half of these subjects would have died of the disease in a short time.

MR. C. MARTIN of Birmingham read a paper on

CONSERVATIVE SURGERY OF THE OVARY.

He said that the physiologic value of the ovaries could be best realized by noting the effect on patients in whom both glands have been removed. The patient becomes sterile, menstruation ceases, atrophy of the vulva, vagina, and uterus takes place, nervous symptoms appear, and there is a tendency to obesity. If only a portion of the gland is left behind the nervous symptoms do not appear, and for this reason an attempt should be made to save a part of one ovary if possible. An exception is in the case of sarcoma of one ovary; here both organs should be removed because the disease is likely to recur in the other ovary. He spoke of the value of ignipuncture in cystic disease of the ovary and chronic ovaritis; he had tried it in fourteen cases, with seven certain cures, and in one case the woman, who had been sterile before, became pregnant three months afterward.

DR. A. LAPTHORN SMITH of Montreal read a paper on

THE BEST OPERATION FOR THE CURE OF DISPLACEMENTS OF THE UTERUS.

The conclusions to which the author had come were based, first, upon his own personal experience of 111 ventrofixations, and 89 Alexander operations; second, upon the experience of forty first-class operators, Fellows of the American Gynecological Society, who had among them performed about 2500 ventrofixations or suspensions of the uterus, and third, upon his recent visit to the leading gynecologists of Europe, whom he had seen performing vaginal fixation. His own experience with Alexander's operation had been all that could be desired—no difficulty in finding the ligaments, no hernia, only one relapse, and no trouble in subsequent labors. With ventrofixation the cases had been much more serious because he had only performed it when there were diseased tubes causing fixation of the uterus. One patient had died, one had relapsed, one had a hernia, two had miscarried, and three had had normal labor; in seven cases a buried stitch had required removal subsequently. Out of the cases reported by other operators, above mentioned, there had been 146 pregnancies, in 36 of which there had been pain, miscarriage, or difficult labor, requiring obstetric

operations, and two or three women had died. Most of these operators had abandoned fixation, and now perform suspension by stitching the round ligaments to the abdominal wall. As a result, however, of what he had recently seen on the Continent, he would now abandon Alexander's operation, ventrofixation, and ventrosuspension, and treat all these patients in future by vaginal shortening of the round ligaments, which had the following advantages: (1) It is very easy; (2) it can be done very quickly; (3) it should have no mortality; (4) it is free from subsequent pain; (5) it will do as well for cases of retroversion with fixation as for those in which the uterus is freely movable; (6) it does not interfere at all with subsequent labors or pregnancies; (7) it does not leave any painful wound or unsightly scar, women being more willing to have an operation done in the vagina than on the abdomen.

Section in Medicine.

First Day—July 27th.

Dr. George W. Balfour, President of the Section, delivered the opening address, his subject being

personal experience of an almost forgotten episode in medical history.

He said, in part: "There are not many now living who remember the time when blood-letting was the panacea for almost every ailment; when patients could no longer be safely bled, they were leeched or cupped. There must be, however, survivors of the time when it was taught that in complicated pneumonia much confidence was to be placed in blood-letting, and that the only essential factor of the prognosis was the day of the disease on which the treatment was commenced. This treatment sometimes failed when delayed more than two or three days from the commencement of the disease. Such were the earliest lessons in medicine that I received, lessons which were daily exemplified in the wards of the old Royal Infirmary.

"Within a year of my graduation, I made my way to Vienna with the view of studying homeopathy. At first, I occupied my time in improving my knowledge of percussion and auscultation under the world-renowned Skoda. You may imagine my astonishment when I found that in his wards the severest cases of pneumonia were treated with poultices and regulated doses of extractum graminis (hay tea), and nothing else, unless much pain was complained of, when a few grains of Dover's powder were superadded. It was truly astonishing to behold in bewildering amazement a pneumonia melting away under the magic influence of a decilliionth of a grain of phosphosus, but it was indeed a *reductio ad absurdum* to find this magic influence emulated by the virtures of hay tea and to be told by Skoda that pneumonia was a disease that tended not to dissolution but to resolution.

"Hahnemann raised to a paramount position one of the many theories advanced by Hippocrates, and enunciated the doctrine that by it alone could disease not only be cured *tuto, cito, et jucunde*, but silently and at once extinguished. In this respect homeopathy was the Eighteenth-Century analogue of our returning antitoxin treatment. Fortunately, the excellent results obtained by Skoda with the hay tea sufficed to dispel the cloud of mysticism evolved by Hahnemann and his school, while the success of Dietl in the same class of cases in another hospital with simply *aqua colorata* showed that there was no specific even in hay tea, and confirmed the conclusion that pneumonia tended not to dissolution but to resolution, and that the large blood-lettings thought necessary for its treatment were to say the least, uncalled for.

"Upon my return from Vienna I read to the Medico-Chirurgical Society of Edinburgh a report of what I had observed in the wards of Skoda, with the account of 392 cases of pneumonia treated on what might be termed expectant principles. I pointed out that the Vienna cases were certainly not less sthenic than those in Edinburgh; and they had the disadvantage of being daily auscultated, discussed, percussed, and lectured over, and that they had not the advantage of having been freely bled, yet their mortality was only 13.7 per cent. My words fell on deaf ears, and the conclusion arrived at may be very well summed up in the words of one of the ablest physicians of the day—Dr. John Gairdner: 'Nothing was better established than the good effect of blood-letting in Edinburgh, whatever might be the case in Vienna.'

"After this, we had a war of opinions in regard to whether the difference in results was due to the better knowledge of the natural history of the disease, and of its pathology, and to the actual change in the type of the disease, which no longer required the same heroic remedies.

"We are now on the threshold of new discoveries and of quite a new pathology, which seem destined to become of the highest importance for the well being of mankind. It is well, however, in the light of the past, to remember that diseases may be recovered from under many different forms of treatment. The practical certainties of our art in all ages have been sufficient for the welfare of mankind. We must be careful never to subject ourselves to any vague ideas of what may possibly be curative, but hold to that which is the paramount object of our art—the relief of suffering."

Dr. James Grant remarked that in Canada venesection, while rarely practised is, nevertheless, still in use.

Dr. Alexander James opened the discussion upon

clinical varieties of hepatic cirrhosis,

considering both the clinical and the pathological aspects of the disease, laying particular stress upon the latter. The point of chief interest brought out by the discussion was the prevalent opinion that cirrhosis of the liver is not to be laid so much as formerly to the door of alcoholism and dietary indiscretion. Dr. Allison maintained that while alcohol predisposed, another factor in causation must be found. Dr. Osler said that sight should not be lost of certain forms due to bacterial invasion, and he read in this connection a paper by Dr. Adami of Montreal upon the bacteriology of progressive cirrhosis. He later exhibited slides illustrating the remarks made. Professor Rosenstein of Leyden gave it as his opinion that in Holland, at least, so much stress as in the past should

not be attached to alcohol as a positive factor. Professor Gerhardt referred to the occasional occurrence of phosphorus poisoning in this connection, and Dr. Drummond and others called attention to cirrhosis occurring with enlarged spleen and pseudoleukemia.

SECTION IN SURGERY.

FIRST DAY—JULY 27TH.

The proceedings of the Section in Surgery were opened by an address upon

MODERN OPERATING-THEATERS,

by the President of the Section, DR. JOHN DUNCAN of Edinburgh. He prefaced the subject of his remarks by a brief description of the advance that has been made in medical teaching in Edinburgh during the past forty years, laying special stress upon the examination system so-called. Formerly examinations were meant to eliminate the useless; now, they dominate the teaching. Among the examiners, the doctrine is inculcated that a candidate for a medical diploma is not a finished practitioner familiar with every side light and detail, but the chief business of the teacher is to make men think, and of the examiner, to find out how far that has been successful. Clinical teaching has come to the fore, and what is practicable receives the most attention. Laboratories and museums are now attached to every department in our new university buildings and in the associated schools. The antiseptic system of surgery has opened so wide a field to the young surgeon and the clinical material has become so abundant that arrangements are being made whereby a surgical theater shall be placed at the disposal of each set of wards. The glorification of mere manual dexterity in surgical work has greatly diminished. If one knows what to do there is little difficulty in doing it. A surgical operation, therefore, has come to be regarded as an incident in a case, and the operating-theater has become an appendage to the wards.

The speaker said he was not of those who have great faith in surgical upholstery. The expense of transforming cleanly and well ventilated theaters into structures of tiles and glass is unnecessary. It may be said that it is all in the right direction, but some consideration should be given to the desirability of expending the money of a charity in costly reconstruction. Smooth and impermeable materials are not necessarily those which are most easily rendered aseptic. A good wooden floor can be made antiseptic and as satisfactory as its modern substitute. The emanations from spectators, from the operator and his assistants are more dangerous than those from the walls and floor, and the time may come when the patient, surgeons, and assistants, having been rendered from top to toe cutaneously aseptic, will cover each orifice of the body with an antiseptic mask, and, clothing themselves in a raiment scientifically pure, shall pass into an atmosphere freed from germs by the air-pump and by heat. Our ingenuity need not be directed to the condition of the air which may be trusted to efficient ventilation and the germicidal action of the tissues. It would be unfortunate if in cases of antiseptic failure the surgeons should be led to seek in unfavorable surroundings a loop-hole from escape of self-blame, or to believe that he cannot operate with perfect success save in a glass case or a crystal palace. The skin, the instruments, and the apparatus are the true objects of our care.

The use of electricity in surgery is undoubtedly extending. In the matter of lighting, there are surgical operations and investigations which cannot be satisfactorily accomplished without it. The surgical value of rendering the body diaphanous by the Röntgen-rays has been amply proved. The electric cautery has this advantage over others that it can be placed in position before being heated. The speaker had preached in season and out of season the surgical uses of electrolysis, but he felt assured that even now it does not meet with the appreciation it deserves. In cirsoid aneurism no other treatment can be compared with it for a moment. In nevus, especially, when it is desirable to avoid a scar, there is nothing so sure and so safe. It does excellently in some forms of agioma; it gives good results in goiter; it is an efficient depilatory.

PROFESSOR BENNETT of Dublin in opening the discussion upon

INJURIES OF THE ELBOW-JOINT,

called attention to the ease with which an incomplete dislocation of the ulna and radius backward might escape detection, and to the fact that in compound separation of the lower epiphysis of the humerus the elbow-joint is not opened because the lower end of the diaphysis is torn out of its periosteum, and thus the ligaments attached to the other end of the humerus are not ruptured. He illustrated the chief point in his paper by a diagram that in fractures at this point it is the lower end of the humerus which is injured, and not the process of the ulna. It is difficult to give a clear idea of this, but it may be said that the broken pieces slip from their places and prevent a proper reduction of the fracture. The removal of a part of the ulnar process is, therefore, not indicated, and attention should be directed to the humerus following whatever method may be indicated by the use of the X-rays.

DR. ROBERTS of Philadelphia read the next communication, which gave rise to much diversified criticism. He advocated, in fractures of the lower end of the humerus, fastening the fragments together with metal nails in cases in which there was any difficulty in keeping them in good position, and he further advised the adoption of the extended position in putting up the limb in splints after any injury of the joint. Professor Chiene expressed himself in favor of the flexed position except in cases of separation of the olecranon, or when the patient was kept in a recumbent position. Mr. Keetley held an opposite view to Professor Bennett's as to the reason why the elbow-joint was not attacked by septic arthritis in cases of compound separation of the epiphysis at the lower end of the humerus, and said that the elbow-joint is not usually opened.

MR. JORDAN LLOYD of Birmingham stated that the dislocation of the elbow is a rare injury, and that sep-

aration of the lower end of the humerus is much more common; an anesthetic is necessary in order to make a satisfactory diagnosis in many of the cases. Force applied to the olecranon may easily cause fracture of the humerus. Opinions differ as to the best position, but few men are ready to accept the procedure advocated by Dr. Roberts—nailing together the fragments.

In a discussion following the reading by MR. BUSH of Bristol of a paper reporting two cases of gastric ulcer treated by sponging out the peritoneal cavity and suturing the ulcer, the general opinion was advanced by other speakers that thorough irrigation is the only method worthy of recommendation in this connection.

In the second day's session of the Surgical Section, SIR WILLIAM STOKES of Dublin spoke upon the operative treatment of exophthalmic goiter, in the course of which he stated that in these operations the thyroid gland requires most careful handling in order to prevent rupture of the follicles and consequent absorption of the secretion into the general circulation with acute systemic poisoning. The striking point in the method advocated by him is treatment by the open method, the gland substance being allowed thus to dessicate in the process of healing, while a sufficient portion remain to carry on its function. Professor Kocher of Berne, an expert in this department of surgery, gave a qualified sanction to this method.

(To be continued.)

REVIEWS.

BRIEF ESSAYS ON ORTHOPEDIC SURGERY. Edited by NEWTON M. SHAFFER, M.D., Surgeon-in Chief to the New York Orthopedic Dispensary and Hospital, etc. New York: D. Appleton & Co., 1898.

THIS is a collection of six articles attempting to define the scope of orthopedic surgery, the author taking the ultra-conservative position of subordinating all operative interference to most prolonged trials of the various mechanico-therapeutic devices at our disposal. Such a limitation of this special department of surgery has been rightly contested. The orthopedist would sacrifice none of his individuality of being in a class by himself if he judiciously and impartially applies the principles of operative surgery together with mechanico-therapeutics.

PROCEEDINGS OF THE SEVENTH ANNUAL MEETING OF THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES. Edited by JAMES E. PILCHER, M.D., Captain in the Medical Department of the United States Army. Columbus, O.: Berlin Printing Co.

THIS report contains a number of articles which are of almost as much interest to the civilian surgeon as to his "brother in arms." The work of the Association was divided into subject-groups, which will indicate the scope of its influence and aims. Among these groups we note the subjects, "Naval Hygiene," "Military Personal Identification," and "Clothing and Accoutrements." Under the latter heading we must make special mention of a very able and interesting demonstration of "Accoutrements for the Infantry Soldier," by Deputy Surgeon-General W. S. Oliver, British Army Medical Department. There are valuable contributions on military physical training, transportation of the disabled, and sanitary work in the National Guard. The volume is a model of press work, and bears the seal of the Association in gold on its simple green cover.

MANUAL OF OPERATIVE SURGERY. Edited by H. J. WARING, M.S., M.B., B.S.C., F.R.C.S., Demonstrator of Operative Surgery and Surgical Registrar, St. Bartholomew's Hospital, London, etc. New York: The MacMillan Co., 1898.

CONTRARY to the plan of other manuals on operative surgery, the author at once introduces the student to the more formidable operations on the gastro-intestinal tract, thereafter passing on to the consideration of minor operations. Such methods may be obligatory in teaching operative surgery on the cadaver when the anatomical material is limited, but a text-book is the place for a logical consideration of surgical technics and the order should be from the simple to the complex.

The introduction deals briefly with the preliminary steps to operations. The list of operations is very complete and the descriptions are concise and are amply illustrated. Preceding each operation are the indications calling for its performance.

In the description of gastro-enterostomy it is not stated whether the anterior (Wœlffler) or the posterior (Von Hacker) method is to be followed. Throughout the description of operations on the pelvic viscera the invaluable assistance rendered by the Trendelenburg position is not brought forth. A description of internal urethrotomy is lacking. A little more attention might have been given to tenorrhaphy. We deprecate the use of so formidable an instrument as Belocq's canula in tamponing the posterior nares: a catheter will answer the purpose better.

The purpose of the reviewer in noting these slight shortcomings is only to emphasize the superior merit of the remainder of the book. It is complete, thorough, and as ample for the practitioner as for the student. It abounds in valuable hints and suggestions and we feel certain that it will prove most acceptable in a field which is by no means over-crowded. In its 644 pages it contains 420 illustrations which serve to elucidate the text admirably. The bookmaking is excellent.

STREET CLEANING AND THE DISPOSAL OF A CITY'S WASTES: METHODS AND RESULTS AND THE EFFECT UPON PUBLIC HEALTH, PUBLIC MORALS, AND MUNICIPAL PROSPERITY. By GEO. E. WARING, JR., Commissioner of Street Cleaning in the City of New York. New York: Doubleday & McClure Co., 1898.

THE author of this book of 223 pages has done valuable service to the cause of municipal sanitation. The style of the book is straightforward and direct. It contains a brief but comprehensive account of the history, organization, and work of the Street Cleaning Department

of the City of New York. He discusses the difficulties surrounding the position of Commissioner of Street Cleaning and presents clearly and strongly the political toils in which every member of the force finds himself involved when politics is the controlling power. The latter half of the book presents a most interesting and instructive account of street cleaning in the large cities of Europe and Great Britain. Members of Boards of Health will find in this volume many valuable hints and suggestions connected with the sanitation of municipalities. Of especial interest is the detailed account of the most approved method of the disposition of city garbage.

NOTES ON MILITARY HYGIENE. For Officers of the Line. A Syllabus of Lectures formerly delivered at the U. S. Infantry and Cavalry School. By ALFRED A. WOODHULL, LL.D. (Princ.), Lieut.-Colonel, Medical Department United States Army. New York: John Wiley & Sons, 1898.

SPECIAL interest attaches to the subject of military medicine and its many subdivisions at the present time. The little volume under consideration, originally prepared for the use of student officers, has been amplified and improved, the text being changed to correspond with the present army regulations, and with the progress of sanitary science. An essay has been added upon the care of troops in the field, especially in warm climates, which contains a number of particularly timely suggestions.

Under the introductory heading of "Selection of Soldiers," we are given a precise but brief and complete synopsis of the requirements of the recruiting office. Age, proportion of height and weight, chest capacity, effect of drill, and incapacitating deformities are taken up in turn. The rule given for physiologic relation between height and weight to be used as the standard of recruits is: "To and including five feet seven inches, two pounds to the inch, and add seven pounds for every inch above five feet seven inches." This does not appear to be in accord with the rule based upon more recent statistics than those of the War of the Rebellion, as, according to it, we find the maximum height six feet three inches, corresponding to a weight of but 190 pounds, which is certainly below the average. The chapters on military food and clothing, on habitations, and on camp and marches are particularly well written. Altogether this little guide is a valuable contribution to medical literature, and, while it is intended primarily for the use of line officers, cannot fail to be of service to members of the medical staff as well.

ATLAS AND ABSTRACT OF THE DISEASES OF THE LARYNX. By Dr. D. GRÜNWALD, of Munich. Authorized translation from the German. Edited by CHARLES P. GRAYSON, M.D., Lecturer on Laryngology and Rhinology in the University of Pennsylvania. Philadelphia: W. B. Saunders, 1898.

IN the preparation of this laryngologic atlas, the same plan is pursued that was noted in the earlier volume of this series on diseases of the eye. The pictures presented are, at first, variations in normal cases, then alterations of the epiglottis, diseases of the vocal cords, followed by subcordal affections. The different diseases of the ventricular bands are well shown, while seven plates are devoted to pathologic conditions affecting the posterior wall. Diffuse alterations and paralyses are well illustrated, besides which there are numerous microscopic drawings showing the minute structure of the affected tissues. Each picture is accompanied by the data of the case, the previous history of the disease, and the examination of contiguous, as well as of more distant, organs. In this way the physician who has few opportunities of inspecting the larynx in large numbers of cases, and yet wishes to be able to recognize the more important affections, receives valuable training. The method of instruction followed is a clever combination of the didactic and the clinical; the cases are well chosen and the diagnostic analyses concise and accurate.

THERAPEUTIC HINTS.

For Toothache.—

℞ Cocain hydrochlorat. . . . gr. ii
Camphoræ } aa . . gr. lxxx.
Chloralis hydrat. }

Mix, add a few drops of water and triturate until the mixture becomes a clear homogeneous liquid.

Sig. External use. Apply on a bit of absorbent cotton introduced into the dental cavity, renewing the application until the pain ceases.

Benzoate of Mercury in Syphilis.—

℞ Hydrargyri benzoat. . . . gr. iv
Sodii chloridi } aa . . gr. i
Cocain hydrochlorat. }
Aq. dest. . . . . ʒ i.

M. Sig. Fifteen to thirty minims administered hypodermically every day for one month.—*Gancher.*

Nutrient Enema in Cancer of the Stomach.—In case of obliteration of the cardiac or pyloric orifice the following is recommended for rectal alimentation:

℞ Yolk of eggs . . . . No. 2
Dried pepton . . . . ʒ i–ʒ v
Wine . . . . ℥ iv
Bouillon . . . . ʒ viii.

M. Sig. For injection.

For Bronchiectasis.—

℞ Terpinol . . . . *m.* xxx
Ol. olivæ . . . . ʒ iss.

M. Div. in caps. No. XX. Sig. One capsule every two hours.—*Rabow.*

For Pertussis.—

℞ Hydrochlorate of phenocol . gr. xviii–ʒ iss.

M. Div. in chart No. XII. Sig. One powder three times a day.—*Kobert.*

For the Diarrhea of Chlorosis.—

℞ Zincohemol . . . . gr. lxxx
Pulvis aromat. . . . ʒ ii.

M. Div. in chart No. X. Sig. One powder three times a day.—*Limousin.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIII. NEW YORK, SATURDAY, AUGUST 27, 1898. NO. 9.

ORIGINAL ARTICLES.

THE MORPHIN HABIT; ITS TREATMENT, AND THE POSSIBILITY OF ITS CURE.

BY JOHN W. ROBERTSON, M.D.,
OF LIVERMORE, CAL.;
PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE UNIVERSITY OF CALIFORNIA.

THE undue use of morphin, either to relieve pain or for the purpose of re-establishing normal tone to the nervous system, has become so common and its abuse is so closely connected with the same predisposing causes which underlie all neuroses that an inquiry into its symptomatology and treatment seems pertinent. Even of more interest is the study of its causation and the establishment of the fact that, in the great majority of cases, it is as much a result of nervous heredity as is neurasthenia, insanity, epilepsy, or dipsomania. By this is meant that morphomania belongs to the group of functional neuroses which has as a basis the nervous diathesis, and that, when a person possessing this constitution even for a few times experiences the pleasing exhilaration that opium brings he not only becomes addicted to the drug but to such an extent its slave that he will sacrifice all in life that should restrain and stand between him and his appetite, and will barter honor, truth, and all social considerations for the relief of the craving so soon established. As a rule the morphomaniac receives but little sympathy, and while the world readily excuses those persons who become addicted to the habit because of pain, it harshly judges the equally unfortunate who have hereditary compulsion as an excuse.

Opium smoking, so prevalent in China, is to some extent practised in California, for every Chinatown in the State is a focus from which the infection spreads. As a rule, however, it is only the vicious and criminal who resort to these dens, and even this class soon discards the filthy and nauseous surroundings for the more seductive and less expensive needle. Opiophagia, or the eating of opium, while chiefly practised in Oriental countries, was until recently a most common vice in both Great Britain and the United States. Of all forms it is the easiest to conceal and can be practised for a certain time without detection.

The invention of the hypodermic needle and the discovery of cocain have added greatly to the dangers of morphin. It is possible either to smoke or eat opium for a life-time and still not be absolutely unfitted for social life, but the hypodermic use of morphin, combined as it usually is with cocain, soon brings physical and mental disaster, and in a little while the subject becomes a burden either on his family or the public charities.

The symptoms characterizing the morphin habit all refer to an unstable nervous state of either the body or the mind. The bodily symptoms are emaciation, weakness, ataxia, and paresis of the sphincters, which Levinstein and other writers have included under the name of morphinism, in contradistinction to morphinomania, under which term they include loss of will power, moral insanity, imbecility, and other mental perversions. During the first few months the use of the drug apparently gives mental strength and bodily vigor. The victim is exhilarated, moves with alacrity, and life is full of zest hitherto unknown. Neurotic longings and physical infirmities are forgotten, and for the first time, possibly, the patient experiences the sensation of being normal. He is certain of his own mastery, and the honeymoon following the first knowledge of the drug is bliss unspeakable. Not that visions such as De Quincey has familiarized us with are of usual occurrence, or that delusions and hallucinations are generally present; these may come with overdoses of the drug, but in the early stages, at least, they are temporary. The subject, probably beginning with a dose of ¼ of a grain occasionally, soon adopts it as a daily habit, and rapidly increases it to four or five grains, but later, finding that excessive doses are necessary to produce the old-time effect, he becomes alarmed and attempts to stop the drug. He reduces the morphin and possibly resorts to alcohol as a stimulant, but the fight is a losing one, and while he may temporarily reduce the amount he cannot throw aside the habit. Finally, thoroughly frightened, he seeks relief, probably takes some advertised cure and stoutly asserts his freedom, yet secretly indulges to a greater and greater extent, and despairing of any relief that morphin can bring, gradually adds cocain. When this stage is reached all hope of recovery unaided goes. He grows more infirm, more debased physically and morally, until he becomes a pariah among his fellow men. The desire for reform is a real one, and the victims are willing to sacrifice everything they hold dear in life—except morphin, could they only recover.

When fully under the power of morphin and the first pleasurable sensations have disappeared, the bowels become constipated, relieved by occasional diarrhea, the appetite is diminished, and the body emaciates. Frequently there is paresis of the sphincters, both rectal and vesical, and the heart becomes irritable, with a frequent and compressible pulse.

Venereal desire, at first increased by the drug, gradually lessens until mental masturbation takes the place of virile power. The skin becomes sallow, the eyes sunken, the face expressionless, and the gait ataxic. The mental symptoms are equally well-marked. The early effects of the drug are manifested in an increase of mental power and ability to carry out life's routine, but as seen as the habit becomes firmly established, and the victim after a few half-hearted attempts at abstinence finds his only course one of concealment and increase of the drug, he loses all interest in his work and his former pleasures and concentrates his whole energy on supplying himself with the opiate. He neglects business, no longer cares for social life, consorts with those similarly afflicted, and sinks into hopeless physical and mental decadence.

The effect of morphin on the mind, whether for the relief of pain or because of natural inclination, is destructive, and no one can become its victim without lowering of moral tone and loss of will power. A morphinomaniac may theorize as well as ever, but let a few hours elapse without the accustomed stimulant, and his unquiet nerves and uncontrollable longings causes him to jeopardize his soul for the drug, and there is no commandment in the decalogue he would not break in order to gain mental ease. No matter how honorable, upright, and conscientious a man's past life may have been let him become thoroughly addicted to morphin and I would not believe any statement he might make, either with reference to the use of the drug or any subject that concerned his habit. This extends further and clouds his moral perceptions in all relations of life. Authorities even go further than this and claim imbecility with organic brain changes. My experience has been large, and, while I cannot claim to speak authoritatively, yet my own observations do not confirm this statement. I do not deny occasional mental deficiency, yet while at Napa and later when temporarily in charge of the Home for Inebriates, many morphinomaniacs were committed as insane, yet not a single one exhibited either delusion or hallucination, and all were voluntarily committed for the purpose of cure. They showed no mental change on the day of their discharge (and they were all discharged "cured") differing from their condition on admission, yet, in a broader sense of the term they were all insane, that is, morally insane. They could not tell the truth, they were boasters, perhaps not so much in the belief that they would never relapse as in detailing the amount of drug taken. They ridiculed any possibility of relapse, yet many left these institutions and hardly let the day elapse before they were back in their old haunts.

Briefly summarized, morphin does not produce active insanity. Unlike alcohol, which, when long and excessively continued, produces chronic pathologic changes, morphin simply destroys the bloom of the mind, obtunds moral sensibility, and only when excessively used produces temporary mental aberration.

The treatment of these cases is a most difficult matter, and my main reason for dwelling on the nervous and mental state has been in order to show the difficulty of caring properly for these patients, while they are allowed the slightest liberty of person or freedom of judgment. There is certainly no royal road to cure that will in a night charm away desire. The only chance is in the slow and permanent upbuilding of the body and the protection of the patient against himself until his will power can reassert its old mastery.

To stop the drug is the first but not the most difficult step in treatment. Whether it be withdrawn quickly or gradually is a matter of indifference. Our books warn us against the sudden withdrawal of the drug because of probable heart failure. My experience does not bear this out. Certainly fifty patients, many of them *in extremis*, were admitted to Napa as insane, and it is fair to presume that when so radical a step was taken their condition was considered desperate. In every instance they presented the same general appearance—an emaciated body, a haggard face, pale, drawn and expressionless, eyes lusterless, and gait unsteady. They belonged to the dregs of society, and nearly all were graduates of the opium-joints in Chinatown. We could never determine on just what grounds they were committed, as none presented any mental symptoms except of moral degredation. The invariable practice was to shut them in a small room after bathing and supplying them with fresh clothing. This was necessary because they always came with their own clothing lined with morphin powers. Within twenty-four hours they were in a state of frenzy, begging and pleading for relief. Soon they became bedfast, vomited, and occasionally purged a viscid green-like bile peculiar to this disease. Nothing, either medicinally or dietetically, was done for their relief. The breakfast consisted of mush, with syrup and fat bacon, and their other meals were equally unappetiz-

ing. From the sixth to the eighth day they rallied sufficiently to walk around the ward, and in two weeks were usually able to go out and relish their food. Within a month their appetite was voracious. The return to physical health was rapid, and in from six weeks to two months each man was strong, robust, and apparently in full possession of both physical and mental health. They were loud, and possibly honest, in their assertions of reform, but in no single case, with one exception, do I know that the patient did abstain. While death may follow any mode of treatment, our experience demonstrated that sudden withdrawal was not dangerous, even though it seemed heartless.

In private practice the gradual reduction of the drug is the only procedure possible. The patient will not willingly endure the unnecessary suffering entailed by its sudden withdrawal. It is not a difficult matter to gradually reduce the drug from the daily five to ten grains to three-quarters of a grain within the first week, but it will probably take another week to reduce to one-quarter of a grain, and another week still to stop the drug altogether. It is not well to let the patient know when the drug is withdrawn as the physical influence is strong and the mind as well as the body demands treatment. Fortunately we have remedies which greatly assist us in so strengthening the nervous system that it can successfully stand the shock of withdrawal. Strychnin, hypodermically, and the red extract of cinchona internally, are excellent stimulants, and while they are not altogether as beneficial as they are in alcoholism yet they powerfully assist. In the lighter cases, especially in which no cocain has been used, the more serious evidences of shock, vomiting, rapid pulse, and physical prostration, may be slight, but when excessive and long-continued abuse has wrecked the system they will be pronounced and will continue more or less during the withdrawal; in fact, the rapidity of withdrawal must be regulated by the severity of these symptoms.

The strychnin solution should be of a strength of 1 to 200, and of this 10 minims can be used not less than twice, and possibly four or five times, during twenty-four hours. So specific is its action that, should the necessity be great, the system may stand one-half a grain without developing physiologic symptoms. With this, equal parts of red cinchona and fluid extract of cocoa should be prescribed, of which one dram may be taken two or four times daily. But with all this stimulation the system is occasionally rebellious, and the nervous system so unstable that bromid of potash must be added. The object in giving this is to overcome the nervous paroxysms, and when it is resorted to it should be pushed to narcotism. In other words, 90 to 120 grains should be given daily, and while bromism continues the morphin may be fully and finally withdrawn. Even from the beginning of treatment the morphin should never be given alone but always in connection with strychnin, and the patient must be kept in ignorance of the amount of drug taken and especially of its final discontinuance. These excessive doses of strychnin and cinchona are to be decreased as rapidly as possible, and by the end of the second week their administration can be reduced to two doses daily, during the third week to one, and discontinued in the second month, the strychnin to be again resorted to when symptoms demand it. The diet during the first two weeks should consist of milk to which as the appetite returns scraped steak may be added; later a generous diet may be allowed. By the end of six weeks the appetite is usually enormous and the body responds quickly.

By the end of the second month the patient presents every evidence of health, and it is now that the difficult portion of the treatment begins. Before this the services of a special nurse have been necessary, and the patient has welcomed his companionship, but with returning strength he resents surveillance; insists that his moral strength equals his physical, and too often persuades his friends that he is perfectly cured. But such cannot possibly be the case. Whether he stays under supervision or goes home the result is the same. By the end of the third month he becomes restless, irritable, and is the prey to all the old-time neurotic longings. He still asserts his freedom from desire, yet unless carefully watched will resort to coffee, alcohol, or other and stronger stimulants. It may again be necessary to resort to strychnin and bromid, although not necessary to produce bromism. Until several such attacks have been successfully combatted the patient remains in danger of backsliding. At my sanatorium six months is the shortest time for which I will receive such a patient, and the limit may be prolonged to twelve months. A shorter time invariably results in relapses, discouragement, and a return to hopeless slavery. For this reason the great majority of these patients never recover, but, when sufficient time has been successfully expended, and the neurotic taint is not too strong, re-establishment of the will power may proceed to such an extent as to overcome the lessening nervous outbreaks. When there is no hereditary taint, and the disease for which the morphin was originally prescribed can be cured, the prognosis is as hopeful as in cases of non-hereditary alcoholism, but the treatment, even in milder cases must be of at least six-months' duration. To discharge a patient at the end of the second month

because his physical system is restored is a waste of time and effort and can only succeed in very exceptional cases. When the disease has affected the mind to such an extent that organic weakness is present, no treatment can be of benefit. Time and protection of the patient against temptation until he is restored mentally as well as physically is the only rational method of treatment.

THE SYMPTOMS AND TREATMENT OF ZOSTER.

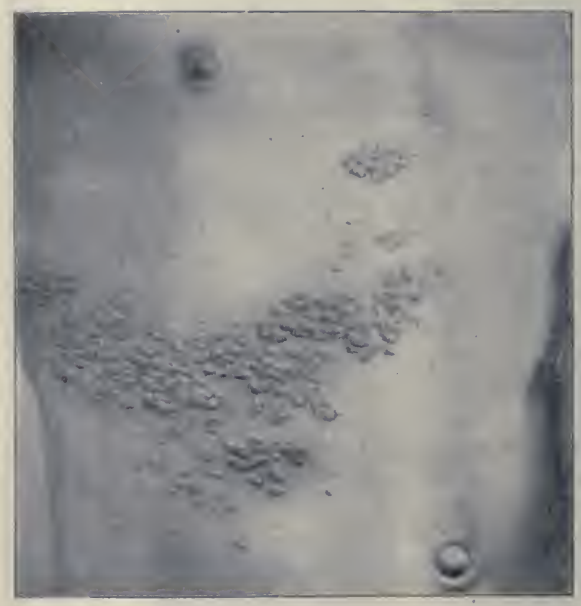
By ELLICE ALGER, M.D.,
OF NEW YORK;
INSTRUCTOR IN DERMATOLOGY IN THE NEW YORK POLYCLINIC; ATTENDING PHYSICIAN IN THE DEMILT DISPENSARY.

ZOSTER, or zona, as it is also called, is one of those diseases of the skin which is much more likely to be presented to the general practitioner for treatment than to the dermatologist. It is probably of much more frequent occurrence than statistics show because it is often unrecognized even by physicians of more than usual skill. The idea that every old woman recognizes it at once under the name of shingles is, I believe, a fallacy. So typical and unvarying, however, are the lesions that a man with a medical training rarely fails to recognize the affection after it has once been explained to him.

The outbreak of the disease is often preceded by several days of vague malaise, possibly by chills and some fever, and frequently by neuralgic pains of varying severity. Then come localized areas of superficial redness over the trunk of a nerve or nerves, which become slightly papular, and in a few hours present the typical appearance of the disease by developing vesicles, which are generally of small size. Each blister is surrounded by a narrow halo of inflammatory redness and the whole number of lesions are grouped together, often in patches, perfectly healthy skin intervening between the vesicles. Sometimes several small vesicles merge in one larger one so that the lesions are of varying size. Unless very large they show no tendency to break down spontaneously, but after a few days the contents, becoming more turbid, is absorbed or dries down as a brown crust which finally falls off without leaving a scar. Several crops of these vesicles may appear and undergo involution during an attack, each crop lasting from three to seven days, and often being preceded by an accession of neuralgic pains. When the disease appears at its commonest site over the intercostal nerves it is very unusual to find patches in the midline of the body, either before or behind, but they are especially prone to appear at the sides, while pressure over the nerve at its point of exit or in any part of its course is productive of very sharp pain. Very unusually there may be a bilateral appearance of the lesions almost meeting in front, an occurrence which, notwithstanding the popular superstition, has no particular significance.

The disease may occur at any time of life and in either sex. It is said to be more frequent in children than adults, but this probably depends largely on the practice of the observer. It has happened in my experience that by far the larger proportion of cases occur in adults past middle age, many of whom came not so much from any disquietude about the eruption, but for relief from the persistent neuralgia. Young adults and children, as a rule, suffer very little pain from this cause, and I can readily see that many would not call a physician at all unless the area involved was quite large.

The disease may occur on almost any part of



Zoster.

the body, the intercostal variety being by far the most common. However, I have never noticed that preference claimed by some authorities for the right side, nor can I see any anatomical basis for the belief. The next most common site is the region supplied by the lumbo-abdominal branches of the spinal cord, and less frequently still the genitocrural branches are involved. The fifth nerve may be affected, involving one side of the forehead and nose, and occasionally presenting a few vesicles on the eyeball itself. I remember one such case in which a permanent opacity was left in one eye by faulty treatment following a mistaken diagnosis. The lesions may appear on the limbs, generally above the elbow and knee, but not necessarily so. In a great many cases there is pronounced

anesthesia of the cutaneous areas over the affected nerve as compared with the opposite side. Sometimes there is a hyperesthesia instead, and either condition may persist for some time after the original lesions have disappeared. Atrophy and local paralysis are said to follow in some cases, but I do not remember having seen any such results personally.

The cause of the disease has been a matter of great dispute, but since about 1860 it has been associated with some doubtful nerve lesions. As patients very seldom die of zoster alone autopsies are not frequent, but in the cases on record lesions have been found in the ganglia on the posterior roots of the spinal nerves, but this is not necessarily a constant lesion for it is seen in tabes, in which disease these ganglia are presumably not affected. It has also been ascribed to a neuritis, and sections of nerves from affected areas substantiate this theory at times but not always. A few authors consider it the work of a germ and refer to what appear to be occasional epidemics. Others ridicule the germ theory. There is probably a certain amount of truth in all these theories for different cases may be differently caused, but until more is known about the microscopic study of nerve tissue the question cannot be settled definitely.

Zoster is more common in the spring and fall, as are all neuralgic troubles, and it has sometimes followed actual violence to a part. It was Crocker, I think, who first called attention to its occurrence in patients who had been subject to a prolonged arsenical treatment. I remember seeing a case of this sort in a child who had for sometime been taking Fowler's solution for the relief of some nervous trouble and presented a well-marked zoster of the chest and arm which subsided in a few days when the arsenic was discontinued.

In this case there was no neuralgia at all. Several of my cases occurred in aged patients who were anemic and debilitated, and in them the disease sometimes persisted a month or more. The pain was very severe and hard to control, depriving them of sleep and rest, and it was easy to see that in subjects of this class it might be a serious matter. In other cases I could find absolutely no cause for the outbreak as the health seemed perfect. In one it seemed to follow worry and hard study. A medical student before examination at the end of his second year developed quite a marked zoster over the left side of his chest, which persisted some time, and a year later just before graduating he developed a second attack, this time one foot being affected. This was rather unusual for very often one attack confers immunity from others.

The prognosis in almost all these cases is good, both as regards life and maintenance of function, but in old and cachectic subjects the duration is longer, the pain greater, and there is a tendency for the lesions to become infected and to ulcerate, leaving scars which we do not expect to occur in the more vigorous subjects.

In a young and healthy subject I do not think the disease requires any treatment except a local protective to prevent the blisters from breaking and becoming infected. The usual method is to cover them freely with a dusting powder and a layer of absorbent cotton and a bandage. Personally, I prefer to treat them as I do burns of the second degree. The blisters are simply laid open with a sterile instrument, no attempt being made to remove the contents, and then the whole region is sopped with the following:

Picric acid	ʒ iss
Citric acid	ʒ iii
Distilled water	℥ ii.

The picric acid converts the fluid in the vesicle into an antiseptic coagulum, the advantage of the citric acid being that it converts the alkaline vesicular fluid into an acid fluid which is much more readily acted upon by the picric acid. The application smarts a trifle at first, but is eventually soothing, and after it is dry it does not interfere with the local application for relief of the pain as do the various ointments and powders; it also hastens cornification and cuts short the crops of vesicles. It would be inadvisable to use it on the face because of the temporary but pronounced yellow stain.

For the relief of the pain there is nothing to be compared to galvanism, the positive pole being applied over the nerve-root and the negative moved slowly over the skin toward the distal extremity or about the patches. The strength of the current depends entirely upon the size of the electrodes. With the ordinary sponges, three to five milliamperes is about all the patient can bear, and his comfort is a good guide in the matter. With larger electrodes ten or twenty milliamperes cause no discomfort. The neuralgia will sometimes disappear for good in two or three minutes, sometimes only for a few hours after a good deal longer application. If the patient is sick in bed the portable faradic battery may be substituted, though in my experience it is not nearly as reliable. Of the drugs which control pain the number is very great, but I think phenacetin, in doses of 5 grains every three or four hours, is the most satisfactory, better than morphin, it seems to me, in pain of this character. However, it must be borne in mind that all the coal-tar products may be depressing to certain subjects, the old and cachectic for instance, and in these the general condition often calls for treatment aside from the local one.

PRACTICAL VERSUS THEORETICAL EXAMINATIONS.

By HENRY W. CATTELL, M.D.,
OF PHILADELPHIA;
SENIOR CORONER'S PHYSICIAN OF PHILADELPHIA.

It is to be deplored that our examinations for medical honors are too often managed in such a way as to require theoretical rather than practical knowledge. The writer has just taken part in conducting the microscopical portion of a competitive examination for resident physicians at the B—— Hospital. It was announced more than a month before the examinations that much importance would be attached to the microscopical diagnosis of the urine and blood. Two minutes were allowed for the inspection of each slide, and the power of the lenses was stated. Only the fine adjustment was permitted to be used, the microscopes being properly focussed for each applicant. The slides chosen contained carefully selected fields of the following objects: (1) a well-stained preparation of blood showing the inter-corpuscular pigmented form of malaria, such as appears in columns H and I of Manson's malarial chart; (2) the characteristic crystals of hemin, and (3) a centrifugated specimen of urine showing numerous pus-cells and granular and pus-casts.

One of the papers—a poor one, as the grade given was 10—was mislaid, so only the result of thirty out of the thirty-one papers handed in are appended in tabulated form. It will be seen that most of the men recognized the first specimen as blood, while the diagnosis of *plasmodium malariæ* was made in but nine cases. The hemin crystals were diagnosed correctly by only five, more than one-half the students (sixteen) considering them some form or other of bacteria, such as bacilli of tuberculosis, anthrax, typhoid fever, diphtheria, actinomycosis, or tetanus. Casts of some sort were recognized by fifteen; those who called them *staphylococcus*, *plasmodium malariæ*, *diplococci*, and tyrosin crystals attaining the lowest averages in the list.

The average grade, allowing 10 out of a possible 33⅓ for the diagnosis of blood in the case of the *plasmodium malariæ*, no matter whether the organism was found or not, was 33.22 out of a possible 100. The oral examinations in surgery, medicine, and therapeutics, conducted by the other members of the staff of the hospital, showed the men to be prepared to answer even the most difficult questions, and revealed a high degree of theoretical knowledge in those taking part therein. No doubt, had the men been called upon to describe the *plasmodium malariæ* or to give the method of preparing Teichmann's crystals, they would have done so with an accuracy and fluency that would have been most pleasing to the examiner.

In a similar examination of thirty nine applicants last year (*International Med. Mag.*, p. 319, May, 1897), a well-stained slide of leukemic blood was correctly diagnosed and described by only three, thirteen others diagnosing it as blood, but attributing its pathological features to pernicious anemia, *plasmodium malariæ*, *diplococci*, etc. The following diagnoses were also made: anthracotic lung, round-celled sarcoma, epithelial cells, hyalin casts, croupous pneumonia, and section of kidney. Cotton fibers in a sample of urine were diagnosed correctly by only six, others calling them linen thread (1), wool fibers (1), some foreign particle (3), unknown (3), muscle fibers (3), fibrin (1), mucin (2), nerve (2), elastic fibers and hair (1), elastic fibers (2), spirals from the sputum of an asthmatic (1), fibrous tissue (4), epithelial, granular, or hyalin casts (5), and cylindroids (6).

For five years I conducted the examinations in gross morbid anatomy at the University of Pennsylvania, and append a few of the answers received from students at the end of the third year of their medical education. Laminated clots from a ruptured aneurism were called a kidney affected with tubercle; a dermoid cyst of the ovary was said to be a carcinomatous mammary gland; appendicitis was mistaken for pyloric stricture, cancer of uterus, malignant growth of stomach, pearl disease, etc.; an intussusception was thought to be an imperforate rectum: parenchymatous nephritis was believed to be tuberculosis of the liver, and croupous pneumonia to be abscess of the liver. On first being told that a typhoid ulcer was a uterus with Fallopian tubes, and that an intussusception of the small intestine was an ovary, the questioner would be inclined to believe that he had not heard correctly; but after the following examination—an actual occurrence—he would think anything possible. A dermoid cyst, with hair, teeth, sebaceous matter, etc., was called diphtheritic membrane of the larynx; acute phthisis with cavities was diagnosed as croupous pneumonia; a large white kidney was pronounced a lardaceous uterus; a cystic kidney appeared to be miliary tuberculosis of the kidney or spleen, and appendicitis to be atrophy of the stomach. In a case of pyosalpinx in which the uterus and its adnexa had been removed at an autopsy held before the class, and the specimen described at a demonstration and an opportunity given twice for each student personally to inspect it, one of the men in the subsequent examination called it a carcinoma of the pyloric end of the stomach. The next is a good example of a too vivid imagination. A falx

No.	Microscope No. 1. Plasmodium Malariæ.	Microscope No. 2. Hemin Crystals.	Microscope No. 3. Pus-cells, Granular and Pus-casts.
1.	Red blood-corpuscles, eosinophiles.	Teased nerve-fibers.	Granular casts, molecular *débris*.
2.	Red blood-corpuscles, macrocytes, microcytes, leucocytes, hematozoa of Laveran.	Tubercle bacilli.	Leucocytes.
3.	Gigantoblasts, progressive pernicious anemia.	Anthrax bacillus.	Epithelial casts.
4.	Red blood-cell stained with eosin; whites, with methyl blue.	Hemin crystals.	Don't know.
5.	Eosinophiles and one basophile.	Uric-acid crystals.	Pus-cells.
6.	Eosinophiles, red corpuscles.	Typhoid bacilli.	
7.	Normal red blood-cells with one white cell.	Amorphous urates from urine, with urates of soda.	Staphylococcus pyogenes.
8.	Specimen of blood showing micro- and macrocytes and poikilocytes, normal casts, pernicious anemia.	Liver with bacteria.	Blood and blood-casts in urine.
9.	Red blood-corpuscles, white corpuscles (leucocytes).	Bacilli (club ends).	Plasmodium malariæ.
10.	Plasmodium malariæ, poikilocytes, red blood-cells, some free pigment, a few poikilocytes.	Uric acid.	Red blood-cells, granular casts, blood-casts, leucocytes.
11.	Reds, mostly normal, one microcyte, nucleated red, large mononuclear leucocyte.	Tubercle bacilli.	Pus-casts, if not blood-casts.
12.	Bright-red, round bodies—red blood-corpuscles, eosin stain; one white blood-corpuscle, hematoxylin stain, one red blood-corpuscle with an intercorpuscular body—either a nucleated red or a plasmodium.	Hemin crystals in a homogeneous mass of gelatinous material, probably destroyed blood-corpuscles boiled together.	Pus-cells in mucous material; also, some white blood-cells; three pus-casts, at the end of one [hyalin albuminoid material can be seen; some granules.
13.	Red blood-disks, lymphocytes, mononuclear plasmodium.	Anthrax.	Diplococcus.
14.	A large number of erythrocytes, a single gigantoblast, some poikilocytes, lymphocytes.	Some drumstick bacilli, other spindle shaped, some granules.	Epithelial cells, epithelial casts, urates.
15.	Fat droplets.	Klebs-Loeffler bacilli.	Numbers of granular cells embedded in a matrix of albuminoid material.
16.	Normal red blood-corpuscles, nucleated red, large mononuclear lymphocyte, poikilocytes.	Bacilli.	Pus-cells, pus-casts, fat drops.
17.	Microcytes, macrocytes, poikilocytes, normal red blood-corpuscles, leucocyte, malaria plasmodium.	Diphtheria bacillus.	Pus-cells, pus-casts, amorphous urates.
18.	Blood-corpuscles, R. B. C., macrocytes, corpuscles containing plasmodium malariæ, white blood-corpuscle, blood.	Triple phosphates, uric-acid crystals, urine.	Microcytes, macrocytes, macroblasts, blood.
19.	Blood specimen, plasmodium malariæ.	Urine specimen, pus-cells, numerous rod-shaped.	Pus.
20.	Numerous red blood-corpuscles, one white blood-corpuscle, plasmodium malariæ in center of field in interior of red blood-corpuscle.	A great many bacilli, some of which are drumstick in shape, suggesting tetanus bacilli.	Pus-corpuscles.
21.	Blood showing normal erythrocytes, a leucocyte containing neutrophilic granules.	Large flat epithelial cell, with urinary crystals overlying it.	Urinary sediment containing blood-disks, epithelial casts, dark granular casts, phosphatic crystals.
22.	Red blood-corpuscles in rouleaux.	Actinomycosis or anthrax. [?]	Urine, granular casts.
23.	Macro- and microcytosis, poikilocytosis (pernicious anemia), few large leucocytes in field.	Bacteria; from shape and size should judge they were anthrax bacilli.	Epithelial and comp. granular tube-casts, loose pus-cells, one group of tyrosin crystals.
24.	Small round cells, one with a few dark granules, another appears entirely blue, probably leucocytes, mostly mononuclear, the granules might be neutrophile granules.	Field full of small rod-like bodies, cannot determine their nature.	Small round cells with granules in them, some arranged in columns, might be mucus or pus-cells.
25.	Eosinophile round cell containing stained granules, white corpuscles with one nucleus; mononuclear leucocytes, multinuclear leucocytes.	Field containing probably tissue with many crystals, nature unknown.	Casts of various sizes and varying in contour, loose cells, probably blood-casts, with free blood-cells.
26.	Plasmodium malariæ.		Epithelial tube-casts.
27.	Large red cells, nucleated small, red nucleated reds, a polynuclear leucocyte, pernicious anemia.	Tetanus bacillus.	
28.	Poikilocyte, eosinophilic cell, reds decreased.		
29.	Fat droplets.		Granular casts, amorphous phosphates, epithelial cells.
30.	(1) Red blood-cells—a roundish, red, biconcave disk; (2) poikilocyte, irregular; (3) lymphocytes—small, dark-purple cells.	Tubercle bacilli in lower and center and right of field—small, thin, black rods.	Fatty casts—long, thin casts covered with fat globules.

cerebri containing a large osteophyte (internal ossifying pachymeningitis), with the longitudinal sinus and portions of the dura covering the upper parts of the cerebral hemispheres, was diagnosed, after a short study, as a bone which had been swallowed and became lodged in the esophagus!

Let us have more practical teaching, and require practical examinations for graduation in our medical schools, for choosing resident physicians in our hospitals, and for license from our medical boards to practise medicine in our several States.

THE PHYSIOLOGIC AND THERAPEUTIC ACTION OF EXTRACT OF THE MAMMARY GLAND.[1]

By JOHN B. SHOBER, M.D.,
OF PHILADELPHIA.

A study of the literature of the subject, and my own observation and experience, has led me to the following conclusions in regard to the physiologic and therapeutic action of the thyroid gland: (1) That when employed in the usual doses, *e.g.*, the equivalent of from 15 to 20 grains daily of the dessicated powder, it acts as a powerful and dangerous depressant to the heart and produces extreme nervous prostration. (2) That it should not be employed for any extended period of time in larger doses than the equivalent of 3 to 6 grains daily of the dessicated powder.

The gratifying results obtained by many observers from its employment in myxedema and psoriasis, and by Dr. Robert Bell in primary carcinoma of the cervix uteri, show that it has a marked influence upon epithelial structure, and it is a powerful lymphatic stimulant. Since it has been shown that diseases of the thyroid gland are often accompanied by an excessive menorrhagia, it would seem that the function of this gland exerts some powerful influence upon the lining membrane of the uterine canal. Having successfully treated four cases of dysmenorrhea with menorrhagia in young married, sterile women, with small doses of dessicated thyroid gland, I am inclined to believe that such is the case.

The fact that fibroid tumors of the uterus are frequently associated with morbid glandular action and cystic degeneration may account for the more or less successful results which have been obtained by the use of thyroid gland in a few cases, these results being due to the action of the gland upon the endometrium and utricular glands which have undergone some morbid change. Owing to these considerations I have long felt that the thyroid gland will be found to have a limited usefulness in the treatment of fibroid tumors. My attention was called to the possible value of mammary-gland extract in the treatment of uterine fibroids by a paper presented by Dr. Robert Bell of Glasgow at the meeting of the British Gynecological Society, held in May, 1896, and published in the *British Gynecological Journal*, xii, pp. 157–170, 1896–1897, also in the *International Medical Magazine*, Philadelphia, v, pp. 379–386, 1896. The paper was entitled the "Treatment of Carcinoma of the Uterus, Certain Forms of Ovarian Disease, and Fibroids of the Uterus by Means of Thyroid, Parotid, and Mammary Gland Therapeutics." The author mentions two cases of fibroid tumors of the uterus and two cases of menorrhagia and dysmenorrhea in which remarkable results were obtained by the use of mammary-gland elixir.

Last November I began the employment of mammary-gland extracts and dessicated powders in the treatment of fibroids of the uterus. The preparations were supplied to me by the Armour Company, and by another company of Chicago. I am now treating four cases of uterine fibroma with the product and it will give me great pleasure to report them briefly on this occasion.

Case I.—Mrs. W., white, aged thirty-two years, the mother of two children, consulted me November 7, 1897. Menstruation was regular and normal until after birth of her last child, 3½ years ago, when she began to experience menorrhagia and dysmenorrhea, her periods lasting five to seven days. About 2½ years ago she became conscious of an abdominal growth which has increased rapidly in size. During the past year she has suffered from increasing menorrhagia and metrorrhagia and all the associated symptoms, and she has become a confirmed opium habitué. During this time she has flowed every two weeks, the flow lasting from seven to ten days.

The growth resembled a pregnancy near term, rising one inch above the umbilicus and extending laterally into both flanks, concealing the anterior superior spines of the ilia. It was so firmly fixed in the pelvis that it had absolutely no range of mobility. The abdominal parieties were tightly stretched over the tumor. She was very anemic and extremely nervous. The following measurements were taken: Girth 37 inches; from symphysis to upper edge of tumor, 7½ inches; lateral measurements, 10½ inches. On December 14th, at the end of a menstruation which had lasted two weeks, I began the use of the powdered extract of mammary gland. Her next period began on January 2d and lasted only three days. It was free but not profuse, there were no clots, and only slight pain. She declared that the medicine seemed to aid her materially in her efforts to stop the use of morphin. The tumor seemed to have contracted laterally. It had slight lateral mobility and its surface felt irregular. The anterior superior spines of the ilia could be located. The girth measurement was the same, the perpendicular measurement was ½ inch smaller, and the lateral measurement was 1½ inches smaller. The cervix had risen in the pelvis. Her next period was delayed eleven days and lasted only three days. It was less free than at any time during the previous two years and she experienced no pain. The tumor had

[1] Read at the Twenty-third Annual Meeting of the American Gynecological Society, Held at Boston, May 24, 25, and 26, 1898.

diminished markedly in size, the upper edge being 1 inch below the level of the umbilicus. It had become more irregular and there was increased range of mobility.

I now began to push the drug, and gradually increased the dose from the equivalent of 12 to 72 grains of the raw gland. On the second day after taking the 72-grain dose she developed intense pain, which was located in the tumor. The growth felt extremely hard, and pressure upon it increased the pain. The treatment was stopped for five days and then resumed in 48-grain doses daily. On March 25th her menses appeared again, being *two weeks overdue*, and lasted only three days. The flow was normal in every respect. On April 4th the following note was made: "The tumor is freely movable in the abdominal cavity and is quite irregular in outline. The abdominal walls are no longer tense from intra-abdominal pressure, but are soft and yielding, and can be lifted away from the tumor. The upper edge is 1 inch below the umbilicus and there is marked lateral contraction. The tumor has been reduced about one-third. Her general health has steadily improved and she is rapidly overcoming the morphin habit." Her next menstruation appeared April 20th, two days earlier. It lasted three days. She is still under treatment.

CASE II.—L. G., colored, single, thirty-two years old, had been conscious of a growth in the abdomen for four years. She was kicked in the stomach five years ago. During the past two years she has had profuse and painful menstruation and free leucorrhea. During the past year she bled about every two weeks, the flow lasting six or seven days. She was anemic, debilitated, and was losing strength.

Upon examination a large, irregular, multinodular fibroid of the uterus was found rising two inches above the umbilicus. The bulk of the tumor was on the right side filling up the right iliac fossa. The patient was placed upon increasing doses of mammary gland on January 13, 1898. Under large doses she developed pain in the tumor, which pain disappeared when the dose was reduced. The following is the record of her menstrual periods: January 15th to 22d, profuse, painful; clots. February 9th to 15th, profuse and painful; three days early. March 8th to 14th, free, pain only during first and second days; one day early. April 7th to 12th, some lumbosacral pain on first and second day; two days late. The menstruation is becoming regular and less profuse. There is no intermediate bleeding. Her general health is improving. She is gaining weight and strength. The tumor has diminished very little in size. She is still under treatment.

CASE III.—M. D., colored, aged thirty-three years. Multinodular fibroid of the uterus. Two small nodules were found on the left lateral wall near the fundus, and from the posterior aspect of the fundus arose an oblong, pedunculated fibroid, about 4 inches long and 3 inches broad. It could be felt rising 2 inches above the pubes, and was freely movable from side to side. During the past two years her menstrual periods have been irregular and frequent, usually lasting only three days, but very painful and rather free, with clots. She began treatment November 27, 1897. She now menstruates regularly without pain, and her general health is improving. The two nodules on the left lateral wall of the uterus can no longer be demonstrated and the pedunculated nodule is now one-half its original size.

CASE IV.—B. Y., colored, aged thirty-four years; had one child and two miscarriages many years ago. She had a large, irregular, multinodular fibroid, extending to within 1½ inches of the umbilicus. It was about 4 inches in breadth and freely movable. Her menses have been irregular, lasting three days. The flow was profuse, with clots, and accompanied by severe pain. She often had a flow lasting two or three days between her regular periods. She began treatment April 2d. Her March period, lasting from the 20th to the 23rd, was profuse and painful. Her next period, April 20th to 23rd, was less painful than at any time during the past year and was not so free as usual. On May 7th she said she felt greatly improved in health. Her clothes, which would not meet before treatment, are now loose.

The influence of mammary-gland products in the treatment of fibroid tumors of the uterus, as shown in these cases, is unusual. These women are all under the age of thirty-five years, and, therefore, the menopause cannot be said to have had any influence upon the results which have been obtained. Without the aid of any other form of treatment the tumors are decreasing in size, and the general health of the patients is steadily improving. Under the influence of the drug, menorrhagia and metrorrhagia cease, and the menstrual periods come on at regular intervals. Even if under a prolonged course of treatment these tumors are not dissipated, we can at least claim that the necessity for operative interference has been delayed. It would be folly to attempt to offer an explanation of the physiologic action of mammary gland. That it has a powerful influence upon the uterine muscle or connective tissue, acting in a manner somewhat similar to ergot, seems evident. The fact that large doses of the gland caused cramp-like or contracting pains in the tumors in Cases I. and II. would seem to bear out this statement.

Yellow Fever at Key West.—It is reported that three unmistakable cases of yellow fever have appeared among the marines at Key West, and as many more suspicious cases. The Naval Station at that point will, therefore, be abandoned and the naval base removed temporarily to Hampton Roads. Steps have been taken to quarantine the Naval Station, and to prevent the spread of yellow fever to the city of Key West. The appearance of yellow fever at Key West is not an unusual experience. It is confidently predicted that the disease will be promptly suppressed.

WAR ARTICLES.

THE SICK AT CAMP WIKOFF.

[From Our Special Correspondent.]

UNITED STATES GENERAL HOSPITAL, CAMP WIKOFF, MONTAUK POINT, L. I., August 22, 1898.

THE hospital staff has been so overburdened with work during the past week that every member of it will rejoice when the last of the transports bearing sick and wounded has arrived from Santiago and discharged its load. One ship after another has been inspected, ambulances and covered wagons have carried the patients either to the general hospital or to the detention-camp, and then, just as we have begun to breathe with some comfort, another vessel arrives, and the program is repeated. Fortunately, the plan of the general hospital allows of the accommodations being increased to an almost unlimited extent, and where we could provide ten days ago for 500 patients, we can now care for nearly twice that number. It was found necessary to extend the wards already up, and to erect additional ones, so that there has been much confusion. We are gradually settling down to a regular routine, however, and things are running smoothly.

A majority of the men brought to the hospital from the transports have been in a condition closely bordering on collapse, and each shows pitiable results of lack of good food and nourishment. The men stood the voyage from Santiago fairly well, as a rule, but all complain that the transports were overcrowded, and that there was a lack of medicines and rations. The care each of the sick received was as good as could be expected under the circumstances, but the majority say that about the only medicines on board were ammonia, camphor, and opium.

Nurses pass down each ambulance train with whisky and hot milk, and minister to each of the men before they are unloaded at the hospital, and more of the same is given them as soon as they are taken to the wards. This treatment has had a wonderful effect in reviving them, and in from twelve to fourteen hours after admission most of the men have been able to do for themselves. I cannot better describe the appearance of these poor fellows than by saying that, without exception, they remind me of pictures of the prisoners in Libby Prison during the Civil War.

The general condition of the patients, aside from exhaustion, is fairly good. There are about 200 cases of typhoid fever, 4 of measles, 30 or more of malaria, and more than 100 of chronic diarrhea and dysentery. The Red-Cross nurses and Sisters of Charity, who arrived last week, are doing most acceptable work, and their help was much needed.

The expected improvement in the water-supply has not materialized as yet, although we look for a change for the better very soon. The matter of latrines, as far as capacity is concerned, promises soon to be a serious question. In the vicinity of the hospital the ground is low, and when a pit is dug it drains from the swamps, so that it is impossible to go more than a foot below the surface before the excavation fills with water. It soon will be necessary to locate the sinks on higher ground some distance from the hospital, which will add greatly to the inconvenience. The constant use of the commodes in the wards by those patients who are able to be out of bed is impracticable, as will readily be understood. The surgeon in charge, Major Ira C. Brown, has established a guard which is on duty day and night at the latrines to prevent the commission of nuisances.

Supplies, both medical and otherwise, are coming in fairly well, but as the hospital fills the requisitions of the different regimental surgeons it is necessary to practice considerable economy. The Red-Cross Society and the Women's National War Relief Association have done splendid work, and the sick and wounded have much to thank them for.

The detention-camp, as well as the grounds of the General Hospital, are now patrolled night and day by mounted guards, and no one is allowed to pass the lines except upon presentation of an order signed by Major Brown. All the patients ill with yellow fever at the isolation camp are doing well and will recover. No case of this disease has developed primarily in the camp.

Up to the present time but twenty wounded men have arrived here. The wounds had all healed prior to their arrival. All speak in words of praise of the first-aid dressings, which were applied on the field immediately upon receipt of the injury.

The burying-ground has been established on a hill overlooking the camp. Up to yesterday there had been five deaths—three from typhoid fever and two from dysentery. The bodies are given a military burial, but on account of the nearness to the hospital wards the firing of a volley and sounding of "taps" has been prohibited. A Protestant chaplain and a Roman Catholic priest are in constant attendance on the patients, and one or the other conducts the burial service.

There have been no cases for the surgical wards as yet. All the typhoid-fever patients, with one exception, are improving. We have discharged, on an average, twenty men a day so far, and expect to keep this up. A post-office has been established under the supervision of Major Brown, and is proving a great convenience to all at the hospital.

THE HEALTH OF SAMPSON'S FLEET.

BY RAYMOND SPEAR, M.D.,

ASSISTANT SURGEON, U. S. N., ON BOARD FLAGSHIP "NEW YORK."

THE health of the navy during its stay in Southern waters has been remarkably good as compared with that of the army. The navy has been exposed to the same tropical diseases as the other branch of the service, but not, however, to so great an extent. The principal diseases that the navy doctors have been fighting to keep out of their ships are yellow fever, dysentery, and malaria. The first has been effectually kept out by quarantine and disinfectant measures; dysentery has not been allowed aboard any of the ships because everybody drinks distilled water only; malaria has been guarded against by selecting places free from the disease for anchorage and by not allowing the men to go ashore. A great many of the ships have now been in Southern waters for nearly eight

months, the first rendezvous having been at Dry Tortugas, where the general health was excellent, not one death being recorded. The "Montgomery" and "Fern" were in Havana harbor after the "Maine" was blown up but there was little sickness on either ship. The health of the divers who were compelled to work in water that was so foul that they could scarcely see two feet in front of them during the day was excellent. These men, as well as their diving-suits were disinfected after each day's work, and the men themselves were given quinin and whisky. None of the men was allowed ashore; all the water they drank was distilled from water obtained on shore, and all articles taken from the wreck were disinfected as soon as they were taken aboard the ships. Coal and provisions were obtained from Key West.

Then Sampson's larger ships were assembled off Santiago. Here, away from the shore, the general health of the men continued to be of the best. The temperature rarely mounted to a higher point than 85° F., and there was almost always a fresh breeze blowing. A certain amount of communication with the Insurgents was necessary. The Cubans were allowed aboard the ships just long enough to transact their business and no longer. When the army landed at Siboney, yellow fever soon made its appearance in its ranks and a quarantine was established by the navy against the army. The exigencies of the situation demanded a certain amount of communication between them but it was limited to official business.

On the "Maria Theresa" there are wreckers and a guard of sailors from the U. S. S. "Potomac." The wreckers obtain their drinking-water from shore, and several cases of diarrhea can be traced to this cause, as the sailors who drink distilled water have been perfectly healthy. Two of the wreckers were taken sick and all on board the Spanish ship were much relieved to learn that their companions were suffering from malaria and not "Yellow Jack." The odor of decaying flesh was still strong and in some of the lower compartments of the ship a lantern would not burn. The gases that have collected in some parts of the vessel are very irritating to the eyes, but the burned saltpetre from the powder may be responsible for this. Amid these unsanitary conditions the wreckers and guard have lived, and on the whole their health has been good.

The navy captured a number of ships in Santiago harbor. Crews were sent to clean and disinfect them, and when they returned to their respective ships, in the course of a week, they were all disinfected, as were their clothes. While aboard the prizes they were made to drink the distilled water they had taken with them. All returned in good health. The crew of a steam launch belonging to the U. S. S. "New York" was compelled to sleep ashore one night at Siboney during the embarkation of the army. The men slept near a stagnant pond at the water's edge and three of them were taken sick with malaria, as proved by examination of their blood. There have been some cases of malaria in the fleet, but most of the patients have old malarial histories.

Grippe has been with the fleet also. Some of the ships are infected with this disease and cases crop out every once in awhile. They are characterized by general weakness, irregular fever, and catarrhal symptoms of the upper respiratory tract. All patients recover in the course of a few days. Until the fleet anchored in Guantanamo Bay there was very little diarrhea. In Santiago Bay, however, it made its appearance and the only explanation that can be given is the difference in temperature between the days and nights, which is considerable. The nights in the bay are considerably cooler than they are out at sea, and as the men usually are careless about the way they sleep it is easy to see how their abdomens can become chilled by exposure to the cool night air. The symptoms these patients present are: diarrhea, abdominal cramps, and moderate fever. The cases run a course usually from one to four or five days. On one of the smaller ships almost all the members of the crew were taken sick with abdominal cramps and diarrhea, and all complained of thirst, while some had slight fever. The drinking-water was examined and found to be full of salt. As soon as this was remedied all recovered.

Venereal diseases, except syphilis, have become a thing of the past. This is readily explained by the fact that most of the men have not been ashore for several months. A few cases of heat exhaustion have been recorded on some of the smaller ships. On the large vessels the firemen have little to do and are having a comparatively easy time.

There have been only three deaths on the ships stationed about Santiago, not counting the men killed in battle. One man committed suicide by shooting himself in the head, another was killed by the explosion of a shell, pieces of which entered his abdomen, and the third killed himself by drinking shellac.

The following is a sample of the daily report of the sick on some of the ships. Many of the cases on this report are minor injuries; there are also some patients left here by other ships which are waiting the arrival of the "Solace."

	Number of people aboard.	Number of sick.
"New York"	658	21
"Oregon"	555	14
"Brooklyn"	560	27
"Massachusetts"	516	21
"Newark"	315	14
"Iowa"	583	8
"Indiana"	562	13
"Dixie"	325	2
"Marblehead"	269	6
"Yankee"	324	5
"Detroit"	250	3
"Vesuvius"	79	0
"Resolute"	122	11
"Scorpion"	111	4
"Vixen"	80	6
"Wompatuck"	32	0
"Osceola"	28	4
Marine Battalion	496	12
	5865	171

This gives an average of about three per cent. sick for the ships, and about two and a half for the Marine battalion.

The navy has lost remarkably few in killed and wounded during the war. The cases of sickness have been so few that the fighting ability of this branch of the Government service has not been impaired in the least.

SANITARY NOTES ON CHICKAMAUGA PARK.

By HENRY I. RAYMOND, M.D.,
MAJOR AND SURGEON, UNITED STATES VOLUNTEERS.

I HAVE been watching with keen interest the experiment of rendering the water of the Park fit for drinking purposes, by use of the Magnon and Berkefeld filters. One month ago these filters were introduced on the grounds, and were liberally supplied to each regiment or separate command with instructions for their use.

Have they been found of practical utility under conditions here existing? The answer is, no. The reason or reasons for the failure of the experiment I will not venture to assign. One Magnon and one Berkefeld filter has been made to supply the Ambulance Company, about 180 strong, with filtered water free of germs and palatable, but this was possible only under the exercise of the greatest vigilance by the officer of the day, and the Quartermaster, who were held to strict accountability by the commanding officer.

Nevertheless, while it has been demonstrated that the thing can be done even under adverse circumstances—hauling of water twice daily from a spring six miles distant from camp and with a command crippled by sickness, and numerically weakened by detached service—the experiment has been trying to the nerves and equanimity of the officers concerned, and we hail with delight a changed condition of affairs by which it is proposed to boil all drinking-water in large iron vessels furnished by the Quartermaster's Department. The water can then be measurably aerated by pouring it from a height in a gentle stream through the air into a barrel for its reception, and cooled by ice if that article can be furnished.

Another similar proposition has been under advisement, namely, to supply the fifteen regiments with twenty barrels of boiled water per day by use of one large boiler guaranteed to supply one thousand barrels per day. The cost of boiler *in situ* not to exceed six hundred dollars; to be of sixty horse-power and with pump running at four or five pounds pressure to force the water into barrels on a platform of sufficient height to permit the water to be drawn off directly into barrels placed in a wagon at the side of platform; or the boiled water could be piped to different localities throughout the Park.

Despite the attempt to secure an unimpeachable water-supply, sickness (typhoid and malarial fevers and diarrheal disease) has been greatly on the increase during the past month. When writing you at the beginning of the experiment there were about three hundred cases of sickness in our Division Hospital; to-day there are nearly six hundred cases.

It is proposed to send North, to-morrow, fifty of these men from the 1st Maine Regiment on furlough by a special train, and fifty more will be transferred to the George M. Sternberg General Hospital which is about to open its doors. This hospital is located near the Widow Glenn field, and is under the immediate charge of Surgeon R. E. Giffen of Nebraska, with Major Charles B. Ewing as Executive Officer. Its personnel further includes a large number of Acting Assistant Surgeons and trained female nurses. Its capacity is five hundred beds, with facility for further expansion. The hospital tents or wards are arranged in a terraced formation, ten deep, running down the hillside with an open platform between each descending ward. All floor space is covered with planed lumber. The hillside furnishes natural drainage. The linen looks immaculate. The influence of this hospital promises to be very great, granting much-needed relief to our overburdened division hospitals.

During the first half of August our Division Ambulance Company has transported about twelve hundred sick. In addition to the overcrowded condition of the division hospitals the regimental dispensaries, now assuming the proportions if not the title of regimental hospitals, are receiving many sick of their own commands, there being in some instances many more than a hundred sick "in quarters" and dispensary.

Regimental hospitals may, perhaps, be suited to the present peace conditions, although it is well known that the experience of the Civil War demonstrated their inadequacy and want of adaptability to the exigencies of the battle-field.

Among the means adopted for the prevention of disease may be mentioned the establishment of regimental camps on the open hillsides where the sun's rays can find free access to the soil unhindered by foliage, and where more perfect drainage can be secured than on the relatively low-lying grounds; also, the frequent removal of camp-sites, that by longer occupancy would lead to soil pollution and air contamination. The flooring of tents with lumber—those pertaining to officers and men, sick and well alike—is a measure calculated to reduce the number of malarial and diarrheal cases to the minimum. Requisitions have been made for lumber in sufficient quantity for the purpose, and this not inconsiderable item of expense has been allowed under a wise and liberal administration of affairs.

To provide a wholesome water-supply and to raise the men from the damp soil while sleeping in the night air, are two very important factors tending toward an amelioration of conditions existing in this camp. Another factor that may be urged in explanation or extenuation of the enormous sick-rate in the camp is the considerable number of men who were physically unsound, and hence unfit for the duties and hardships of camp life, when enlisted. These before receiving their discharges on Surgeon's Certificate of Disability unfortunately have tended to encumber the sick report for a longer or shorter period, as well as to engross the Surgeon's time in the perfecting of their discharge papers, and the board's time in reviewing their papers previous to their being submitted for the action of authority competent to order the discharge.

FEVERS THAT ACCOMPANY AN ARMY.

[Special Correspondence of the Medical News.]

Morro Castle, Santiago de Cuba, August 15, 1898.

After a month in the field with the Fifth Corps of the United States Army operating in the province of Santiago de Cuba, I have been able to see and study, in a general way, the fevers which accompany any large body of men actively engaged in a tropical country, constantly exposed to the sun even during the midday hours when the natives themselves are unable to engage in the ordinary duties necessary to their lazy existence, and who have learned from experience that exposure to the heat during these hours predispose them to the indigenous fevers. This, with an unacclimated people handicapped by the hardships of war, such as insufficient amount and poor quality of food, the bad sanitary conditions that a large body of men constantly moving without baths or change of clothing for days are subjected to, and compelled to drink water that has been contaminated by a fleeing mob of filthy refugees, who bathe, drink, cook, and wash from the same stream, has taken more lives from the United States than all the Spanish shot and shell. The Medical Department has had a very grave question to consider, and the care of the sick has proven to be one which will be given more thought and attention in the future. Medical supplies, doctors and nurses, tentage, and ambulances have not been sufficient for our sick during the past, but those in authority are making herculean efforts to correct what the American people would never forgive, and which would be a blot upon the name of any country whose almost inexhaustible resources will permit of no such neglect.

Leaving Fort Monroe July 3d, on the hospital ship "Relief," were fifteen acting-assistant and volunteer surgeons, among whom were Dr. Senn of Chicago, and his first assistant, Harry A. Greenleaf, all of whom were landed at Siboney on the 7th of July and temporarily assigned to the general hospitals at that place, where all of the wounded up to this time had been transported and cared for. After three days work here we were sent to the front and assigned to different regiments and commands. The writer, being detailed to Batteries G. and H. of the Fourth Artillery, siege train, remained with that command until the 23rd, when he was ordered with Battery G. of the Fourth Artillery to Morro Castle, and is at present acting-surgeon at that fort, the first United States army fort established on the island. During this time I have had to deal only with the sick, there being no wounded, and have noted as carefully as possible under rather trying conditions the symptoms, course, and sequelæ of these fevers.

The prevailing fever, and the one which is often incorrectly diagnosed, and is quite frequently mistaken for some type of malaria, is commonly called "sun fever" in the States, and is often encountered in the Southern States during the harvesting season. This fever, very much resembles malarial fever in its onset, and during its course the symptoms are in a great many respects like those of yellow fever, and undoubtedly have been mistaken for the latter. This, of course, would not be likely to occur in general practice where every case could be closely watched, temperature taken, daily examination of urine made, and where histories would be of some value, but this is vastly different from what we had to contend with in the field during the past month. Histories were of no value whatever, because every soldier has been subjected to the same hardships, and exposed equally to the same hot, tropical sun. Then again, this fever must be differentiated from malaria, and here also there are like symptoms to complicate conditions and make a true diagnosis difficult.

In sun fever, malaria, and yellow fever one meets with very similar symptoms, such as a temperature ranging from 100° to 107° F.; vomiting, in color clear, yellow, and dark; headache, supra-orbital, and post-cervical; pains in the epigastrium, lumbar region, and in all extremities; constipated bowels, and high-colored urine, very small in amount during twenty-four hours. In malaria and sun fever the patient has frequent chills, which differ in some respects, a fact which is of great diagnostic value. In yellow fever and sun fever the conjunctivæ are injected, but the injection is of different color and intensity, which also is a very valuable point in differential diagnosis.

During the past month, during two weeks of which time I have seen as many as 120 of these fever cases daily, I have only seen four true cases of yellow fever. I have often met what I was forced to look upon as suspicious cases, in which albumin was found in large amounts in the urine, the men being promptly isolated and and treated as yellow fever cases, but only in the four instances mentioned have I met with what I consider an infallible sign, and that is the characteristic injected conjunctivæ. This is difficult to describe, but when once seen is never forgotten. It is of a pale-yellow color, generally diffused, and gives the eye a lack of expression and appearance of a sightless one. This should be especially noted in contradistinction to the appearance of the eye in sun fever, in which there is a bright-red injection, the capillaries are well-defined and separated by small areas of healthy conjunctiva, and the expression is that so often seen in the eyes of fever patients. In both yellow fever and sun fever vomiting occurs in the early stages, the color of the vomit in the first named ranging from dark-yellow to black, and finally becoming fixed in character. The vomiting has no especial relation to ingestion of food, while in sun fever it always follows the taking of food, and often even the drinking of water. In the latter it varies from light to yellow in color, has no odor, and does not weaken or depress, as in yellow fever. The two common symptoms of malaria and sun fever are high temperature and chills. In malaria, however, there may be a little morning and evening temperature, while in sun-fever a morning temperature is rarely noted, and the evening temperature is perhaps a degree and a half to two degrees higher than in malarial fever, the difference in surface or skin temperature being perceptible to the touch. There is also a difference in the chill phenomena. In malaria there is the usual rise in temperature, followed by a chill, and then the sweating stage, while in sun-fever the chill accompanies the fever

and there is no distinct sweating stage, the chill being essentially nervous. This fever has been improperly called "acclimating fever," but apparently the natives are as frequently attacked by it and their attacks are quite as severe as those met with among our troops. The natives, however, either from experience or a natural antipathy to work, are immune to a certain extent because they expose themselves but little to the midday sun. Sun-fever has incapacitated our troops more than anything else in Cuba. Upon exposure to the sun or reflected heat for days afterward the men suffer from intense headache and nausea, either to the extent of vomiting or to a degree that interferes with natural digestion, and consequently they lose flesh and become so weak that at the present time there are at least five thousand of them on the island who scarcely have strength to present arms.

The treatment of this fever in the acute stage is simple, and fortunately so, for in time of war some medicine-chests are left behind, and in my little experience I have used but three drugs in a general routine treatment. While the treatment is somewhat heroic, it has been quite satisfactory. Of course, when possible, a full bath or sponge bath is given immediately. This is followed by the administration of magnesia sulphate in half-ounce doses every hour until copious watery stools are passed. Calomel should always be given in ½- to 1-grain doses every hour until from four to six doses have been taken in cases in which the patient is seen in the morning and before fever is apparent. Ol. terebinthinæ should be given in 20- to 30-minim doses three times daily. Water should also be taken in large amounts, and should be well acidulated with lime-juice. Phenacetin, salol, and acetanalid would have been of much value, but were not to be had. The ideal treatment, of course, after the acute stages, is to send the patient where climatic conditions are favorable. This seems rather absurd and impracticable in the case of an army of sick men, but apparently it is the only solution of the question, and the only logical treatment. Up to the present time I have not met with a single case of enteric fever, and while conditions are in every way favorable to its production it is probably not an indigenous fever. Both yellow fever and enteritis will doubtless become epidemic in Santiago before the summer has passed as the city is in a very unsanitary condition and overcrowded. In fevers that accompany an army in a tropical country it seems to me from my small experience that sun fever is the most to be dreaded, and necessarily unavoidable.

STANLEY WARREN, M.D.,
Acting Assistant Surgeon United States Army, Battery G., Fourth Artillery.

MEMORANDA RELATING TO OPERATIONS OF THE MEDICAL DEPARTMENT.

THE following memoranda have just been issued from the Surgeon-General's office at Washington:

Medical Officers.—The number of medical officers allowed by law is inadequate in times of peace. The total number allowed is 192. There are at present thirteen vacancies. The administration of the Surgeon-General's office and the Army Medical Museum requires six. Eleven are on duty at medical-supply depots and as chief surgeons of military departments. One is at the Soldiers' Home; fifty-six are at general hospitals, on hospital ships, and at garrisoned posts. Four have been disabled during the war by sickness. Five are on duty as chief surgeons of army corps. This leaves ninety-six medical officers available for duty with troops in the field. Of these, thirty-five have been appointed brigade surgeons of volunteers and are distributed among the various army corps.

This deficiency in regular medical officers has made it necessary to employ nearly 400 contract surgeons, and more are being employed every day. Most of these doctors from civil life are doing good service, and many of them are thoroughly well-equipped physicians and surgeons with ample hospital experience, but it has been impossible to make a careful selection, owing to the great pressure of business in the Surgeon-General's office, and the urgency has been so great that it has not been practicable to have examining boards to pass upon their qualifications.

In addition to this there have been appointed by the President, eight brigade surgeons with the rank of lieutenant-colonel, twenty-four division surgeons with the rank of major, and sixty-five brigade surgeons; also, three medical officers for each of the regiments of United States Infantry, Cavalry, and Engineers. All volunteer regiments have three medical officers appointed by Governors of States.

General hospitals have been established at Key West, Fla., with a capacity of 755 beds; at Fort McPherson, Ga., 1050; Fort Thomas, Ky., 432; Chickamauga Park (Leiter Hospital), 255; Fort Monroe, Va., 535; Fort Myer, Va., 308. In addition to this several hundred sick and wounded soldiers have been placed in the Marine Hospital on Staten Island, and in civil hospitals in New York and Brooklyn; also, nearly 200 in the civil hospitals in Charleston, and a smaller number in civil hospitals in various parts of the country.

The hospital train, which was equipped for service June 22d, and consists of ten tourist sleepers and a dining-car, has made repeated trips from Camp Thomas, Tampa, and Fernandina, with sick to the general hospitals at Fort McPherson and Fort Thomas, and has proved to be most useful.

The hospital ship "Relief" was purchased May 18th, but owing to delays in preparing her for service did not sail from New York until July 2d. Four days later she arrived at Siboney with an amply supply of medical stores of all kinds and with sixteen doctors. She returned to New York with a load of wounded and was then dispatched to Porto Rico. She is now returning to New York with 260 sick and wounded soldiers.

The hospital ship "Olivette" went with the Fifth Army Corps from Tampa, Fla., to Santiago and brought a load of wounded from that port to New York. She returned to Santiago with supplies and is now en route to New York with 200 patients.

Medical Supplies.—When the troops were ordered from their respective posts into the field, each regiment was required to take with it medical and surgical chests, litters and field supplies for three months. Afterward, medical supplies in ample quantities of all kinds were sent to Tampa for the Fifth Army Corps, about to sail for Cuba, and supplies have subsequently been sent to the several camps that were formed, wants being anticipated as far as possible and requisitions approved promptly on receipt.

Supplies for the army have been furnished from three medical-supply depots: New York, St. Louis, and San Francisco, the latter suppling very largely, by purchases on the Pacific Coast, the troops that went to Manila. The St. Louis depot supplied the camps and regiments in the Mississippi Valley and the West; and the New York depot the camps and expeditions fitted out from the Atlantic Coast.

In addition to general medical supplies in great variety, 1204 medical and surgical chests have been issued, the surgical chests containing surgical instruments and dressings especially designed for the relief of the wounded on the battle-field.

The extent of the demand upon the medical-supply depots is indicated by the following figures, showing the issues of some of the more important articles:

First-aid packets	No.	272,000
Hospital-corps pouches	No.	5797
Orderly pouches	No.	509
Pocket cases	No.	962
Surgeon's field cases	No.	369
Field-operating cases	No.	328
Medical and surgical chests	No.	1204
Litters	No.	2250
Litter slings	No.	7600
Cots and bedsteads, with bedding	No.	18,185
Blankets, gray	No.	23,950
Field desks	No.	440
Quinin pills	No.	7,300,000
Chloroform and ether	Botts.	13,220
Gause, sublimated, metal packages	Pkgs.	100,625
Gauze bandages, three sizes	No.	331,776

Sick and Wounded. — At the present time (August 15th) we have a full record of 40,520 cases of sickness and wounds that occurred among a mean strength of 154,028 men, during the months of May, June, and July. As the average of the three months probably six per cent. of the troops were constantly sick. Reports from commands not yet represented in the statistics are expected daily.

Hospital Corps.—At the outbreak of the war the Hospital Corps consisted of 100 hospital stewards, 103 acting hospital stewards, and 520 privates, making a total of 723. The larger part of this number was ordered with the troops that left their respective stations to the camps of concentration and accompanied the regular regiments in the Fifth Army Corps to Cuba, the smaller part being left behind at the various army posts, they being just enough to take care of the medical property.

Enlistments were at once ordered throughout the country of suitable men for the Hospital Corps, special attention being paid to enlisting nurses, pharmacists, cooks, drivers, mechanics, etc. A good many medical students and young physicians were also accepted.

By means of enlistments and afterward by transfers from volunteer regiments to the Hospital Corps a large number of men were obtained, and to-day there are in service by actual count 5084. Probably 1000 are in service whose enlistment and transfer is not yet reported.

In addition to the members of the Hospital Corps enlisted for the purpose of taking care of our sick and wounded we have employed 141 male and 386 female nurses under contract.

CLINICAL MEMORANDA.

SARCOMA OF THE ORBIT.

By DAVID WEBSTER, M.D.,
OF NEW YORK.

DR. C. P. McC., aged thirty-one years, was referred to me by Dr. Gibney, March 18, 1891, with the following history: Four weeks before his friends thought they noticed a slight protrusion of his right eye and called his attention to it, but he experienced nothing wrong until a week later he began to have double vision on looking upward or to the left. In a very few days the eye began to bulge forward quite perceptibly and the protrusion increased rather rapidly. He had no pain in or about the eye and had done nothing for it. His family history was negative. He denied syphilis. When eight years old he was thrown by a pony and had considerable swelling in his groin. His physician thought it might have to be lanced but succeeded in scattering it. After some years the swelling in his right groin reappeared and was lanced. He had had chronic suppurative otitis media of the right ear, with occasional exacerbations, since infancy. Hearing: right ear, 2/60; left ear, 20/60.

There was marked exophthalmus of the right eye and slight swelling of the lids. A small tumor could be felt through the lower lid at the outer angle of the orbit. This tumor was very firm to the touch. Right eye: vision, 20/70; 20/15 with 1.50 D. cyl. axis 90°. Left eye: vision, 20/30; no improvement with glasses; accommodation normal. Ophthalmometer showed astigmatism, 2. D., against the rule. Hyperphoria R. 2°; no esophoria nor exophoria; abduction 6°, adduction 16°. Visual field of right eye somewhat contracted above and to the temporal side; tension normal. Ophthalmoscopic examination: temporal half of right disk somewhat pale and bluish; a small scleral crescent to temporal side of disk.

The patient was admitted to a bed in the Manhattan Eye and Ear Hospital on March 20th, and having been placed on the operating-table was further examined. His epitrochlear glands were found to be slightly enlarged. His inguinal glands had a "shotty" feel. None of his cervical glands was enlarged. The patient admitted having had gonorrhea many years since, but still denied ever having had a chancre. After due consultation, however, it was decided to defer the operation and to try the effects of antisyphilitic treatment. As the case was thought to be sufficiently grave to justify heroic treatment he was at once put upon iodid of potassium, 60 grains, three times a day, to be increased 15 grains daily, and oleate of mer-

cury, 20 per cent., half a dram being rubbed into a different part of his body or limbs night and morning.

March 23d. The patient complains of pain in his jaw at the angle, and in both eyes. He thinks this is caused by the iodid.

March 25th. The iodid has been increased to 110 grains and he is having half a dram of the oleate of mercury rubbed in three times a day. He has been attacked with severe pain in his toes, for which a liniment and hot fomentations were applied.

April 1st. The eye is not so prominent and the tumor seems to have diminished some. Vision, 20/15 in each eye. As the patient seemed to be improving he was, at his own desire, allowed to go home, with a view to continuing the treatment there and returning to the hospital when indicated.

April 6th. He writes that he is taking 110 minims of a saturated solution of iodid of potassium three times a day and rubbing into his skin half a dram of oleate of mercury twice a day. His foot pains less than it did but he has frequent shooting pains in the eye.

April 10th. He has stopped the oleate because it began to effect his mouth. He has severe pain in his foot every night.

April 15th. He is now taking 120 minims of the iodid solution three times a day. He is actively engaged in professional work. His eye pains some and he thinks he cannot see quite so clearly with it as he did.

April 18th. He continues to suffer with his right foot. The orbital tumor seems not to have made any progress. He has slight headache occasionally, a thing he never had before.

April 23d. He is taking 125 minims of the iodid solution three times a day. The pain in his foot has been relieved by 10-grain doses of antikamnia.

May 8th. The patient asks permission to place himself under the treatment of a quack who promises to remove the tumor without operation.

July 1st. The quack has failed to help him. The eye protrudes more and is now almost constantly painful. The pain keeps him awake nights.

July 6th. Readmitted to the hospital. There is considerably increased exophthalmus, the eye being pushed directly forward but with an upward displacement, being on a higher level than the fellow eye, and solid fulness can be felt between the infra-orbital edge and the globe. There is no swelling of the lids or of the conjunctiva. There is scarcely any redness noticeable anywhere about the eye. The eyeball itself is, apparently, perfectly sound. Vision, 20/70; 20/20 with —2 D. cyl. axis 90°. With my consent the patient consulted Dr. Knapp, who said he believed the neoplasm to be a periorbital sarcoma, and advised its removal. The patient was, accordingly, placed under ether, and the eye was washed with bichloride-of-mercury solution, 1–5000. With a scalpel an incision was made along the lower orbital margin and curved around the external canthus along the supra-orbital edge to one-third its extent. The included tissues were then dissected up and turned upward over the eyeball, the conjunctival cul-de-sac being carried with the flap. The tumor, which was thus exposed, was then removed piecemeal, the sclera being exposed on one side and the wall of the orbit on the other. The tumor embraced the eyeball, as it were, in a socket, extending far back toward the apex of the orbit. The anatomic elements in the orbit were all destroyed except in the superonasal region, where the growth did not extend. The orbital plate of the superior maxillary bone was found to have undergone absorption from pressure of the growth. The hemorrhage having been arrested and the wound cleansed, the flap was replaced in position and sutured. The wound was dressed with bichlorid gauze and cotton and a bandage applied.

July 7th. There has been considerable bleeding from the wound, the blood saturating the dressings. Upon removing the dressings and washing the eye the wound seemed to be healing by primary union.

July 8th. The bandage was again stained with blood, which seemed to come through the palpebral fissure.

July 9th. Inflammation has set in. There is swelling of the lids and the dressings are saturated with bloody exudation. Vision: perception of light.

Panophthalmitis set in soon after this, and the patient remained in the hospital until August 14th, nearly six weeks after the operation, when he was discharged with a sightless and shrunken eyeball.

September 22d. His family physician says there is no return of the growth. The entire right side of the face, nose, teeth, and tongue have been numb since the operation. He has no pain in or around the orbit, but a very disagreeable feeling.

The tumor never returned in the orbit. The next I heard of the patient was that he died on April 25, 1892, about nine months after the removal of the orbital tumor, of *cancer of the throat*. I am under the impression that the tumor was examined microscopically and found to be a sarcoma, but the present pathologists of the hospital are unable to find any record of such examination. If I had removed the eyeball at the time of the operation, the patient would have been spared weeks of suffering.

MIDDLE MENINGEAL HEMORRHAGE DUE TO SKULL-FRACTURE; OPERATION; RECOVERY.

By EDGAR P. COOK, Jr., M.D.,
of Chicago;
Interne in Cook County Hospital.

F. S., aged twenty-two years, a dentist, was admitted into the Cook County Hospital at 11.20 P.M., October 4, 1897, in a comatose condition. His father stated that the patient had come home about three hours before and complained that he had been struck on the head by a man and did not feel well. He assured his parents that there was no occasion for alarm, for he "would be all right"; but instead of getting better he gradually became stuporous and passed into the unconscious condition present on his admission into the hospital. Two physicians had examined the patient at his home and advised the application of an ice-bag to the head.

It was subsequently learned from the patient himself that a man had struck him on the side of the head with the bare fist in a quarrel. The blow was delivered at close range as he was walking past his assailant, and although it was sufficient to stagger him he did not fall. On the contrary he was able to walk nearly a mile to his home. At the time he felt dizzy but he did not lose consciousness until at least half an hour later.

When admitted into the hospital, the patient lay in complete coma; it was impossible to arouse him on making strong supra-orbital pressure. On irritation, he moved the left arm and leg but there was nearly complete paralysis of the right upper and lower extremities. No special change in the facial muscles was noted. The pupils were unequal, the left being widely dilated and not reacting to light. The pulse was 48, regular, and full. The temperature was normal and the respirations were slow and regular, but not stertorous. The patient retched frequently but did not vomit. Occasional convulsive tremors passed over the body. The bladder and rectum were normal. Over the left temporal muscle, above and in front of the ear, was a slight contusion but careful examination failed to reveal any local signs of skull-fracture.

A diagnosis of middle meningeal hemorrhage was made and immediate trephining advised. The entire head was shaved and cleansed surgically. Under ether anesthesia a horse-shoe-shaped incision was made over the left temporoparietal region, beginning anteriorly just behind the temporal artery, to avoid wounding, and continuing upward and backward behind the ear, the center of the incision being directly above the left ear midway between the auricle and the sagittal suture. A flap consisting of the periosteum and superimposed muscular and cutaneous tissues was turned down, disclosing at the base of the flap a depressed, comminuted fracture of the squamous portion of the temporal bone of the size of a half-dollar. The fragments of bone were elevated and removed, exposing a large, dark, bulging blood-clot underneath. As the removal of part of the clot started brisk arterial hemorrhage, the opening in the skull was rapidly enlarged with rongeur forceps in order to expose the field better. More clot was now removed and the source of the hemorrhage was discovered, the blood spurting in a stream from a small opening in the dura, which was pushed away some distance from the skull by the clot of blood. To arrest the hemorrhage a round needle, threaded with fine silk, was passed through the dura near the bleeding-point and the thread used as a tractor to pucker up the dura; the bleeding-point was then easily caught up with hemostatic forceps, a procedure previously tried unsuccessfully, as the forceps merely pushed away the tense dura without grasping any part of it. The active hemorrhage having been checked, the artery could be seen coursing through the dura as a light line on a darker background; judging from its anatomical relations the vessel was the posterior branch of the left middle meningeal artery. Two fine silk ligatures were passed through the dura and around the artery, one on each side of the point of rupture. On tying these and removing the forceps the arterial hemorrhage was entirely controlled. The balance of the blood-clot was now gently removed, the little finger being used for this purpose. The clot was of the size of a tea-cup, at least, and on its removal a large area of the internal surface of the petrous portion of the temporal bone was exposed to sight and touch; the clot extended to the base of the skull and also a considerable distance toward the vertex. The dura did not return to its normal position on the removal of the clot and a large vacant space remained inside the skull. Into this space a loose iodoform gauze packing was introduced, one end being brought out at the lower posterior point of the scalp wound. Another gauze drain was carried through and through at the base of the flap outside of the skull. The external wound was closed with interrupted silkworm-gut sutures, leaving provisional sutures at each end of the flap where the gauze drains protruded. The usual large aseptic dressing was then applied.

The patient returned from the operation in good condition at 3 A.M., October 5, 1897. The pulse was 64 and the respirations normal. The pupils were equal and reacted normally. Six hours later the patient was awake and perfectly rational. He said he felt all right and wanted to go home. All paralysis of the extremities had disappeared; there was a slight impairment of the muscular action of the right side of the face but no definite paralysis. Hearing was normal. The subsequent course of the case was uneventful. The drain into the skull was removed at the end of thirty-six hours and the other drain twenty-four hours later, and the wound closed by tying the secondary sutures. Union was by primary intention.

The patient left the hospital at the end of four weeks. There was no paralysis or disturbance of special sense. At the site of the fracture just anterior to the left external auditory meatus the brain pulsation can be noted on close inspection beneath the temporal muscle, showing that the dura has been restored to its normal site.

I am indebted to Drs. Davison, Bassoe, and Ford for assistance in the operation. The case is of interest, presenting, as it does, both in the history and the physical findings, the classical picture of internal hemorrhage from the middle meningeal artery. It also illustrates how so serious a lesion may arise from slight external violence, and emphasizes the value of prompt diagnosis and immediate surgical interference in a class of cases where the expectant plan of treatment has almost invariably resulted fatally.

THERAPEUTIC NOTES.

Blood Clysters in Pulmonary Tuberculosis and Anemia.—WHITTAKER (*Jour. Amer. Med. Assoc.*, August 6, 1898) calls attention to the polycythemia which exists at high altitudes. At 14,000 feet in the Cordilleras, in Peru, the number of red blood-cells is almost double the number found in blood at the sea level. The increase at less high altitudes is proportional. To this polycythemia, not less than to the bracing air and out-of-door life, he attributes the ease with which tuberculosis is cured in

mountain-resorts. By artificially reducing the pressure in a room in which a rabbit is kept, it has been found possible to cause a corresponding increase in the number of his red cells, and a corresponding increase in the amount of oxygen which he absorbs. Even in so short a time as four weeks, this difference amounted to about one-fourth. Whittaker tried similar experiments upon men, but failed to get the same results, perhaps on account of the relatively small size of the cabinet, and the lack of an abundance of fresh air.

Attempts, however, to supply the system with a daily quantity of ready-made blood, were more successful. To prevent coagulation, preserve the life of the corpuscles, and to intensify the alkalescence of blood, he adds to it a little salt, soda, and milk sugar. Some persons are able to drink blood without repugnance, but taken in this way it has no particular advantages over other equally nutritious food, as it has to be digested before it can be absorbed. He found it, therefore, much better to introduce it into the intestine, as may readily be accomplished in the following manner:

The patient is directed to add a teaspoonful of salt, two tablespoonfuls of soda and a tablespoonful of sugar of milk to a pint of boiled water, and to pour one-half of this quantity into a clean glass jar, requesting the butcher to add to it one pint of fresh calf's blood. The fluid should be injected at once, or if this is not practicable, the jar should be put upon ice and the contents used within twelve hours. In no case should the fluid be heated, as heating favors coagulation and dissolution of the blood. This quantity should be introduced every night, and in bad cases twice a day, morning and evening. In all cases the bowel should be previously washed out with a simple injection of water. As a rule, to which there are many exceptions, the blood is entirely absorbed, so that often not even a trace of it is found on irrigating the bowel on the following morning.

The injection should be made with the patient lying on the left side. For fifteen minutes thereafter he should lie upon the back, and then go upon the right side for another quarter-hour, so as to favor the distribution of the fluid throughout the colon.

The results obtained by this treatment in one case of pernicious anemia, and in cases of phthisis without fever, were most satisfactory. Patients with a high fever were not benefited. One patient with fever and repeated hemoptyses, had such copious bloody expectoration, that the clysters were abandoned for fear that they might tend to keep up the hemorrhages. There was no change after the discontinuance of the injections, however, and in no case did any ill effects follow their use.

The injections give absolutely no annoyance to the patient, as may well be inferred from their bland character; and they are heartily commended as being far more nutritious than any others yet devised.

Treatment of Hemorrhage in Typhoid Fever.—MCCORMICK (*Penn. Med. Journal*, July, 1898) says that the treatment of hemorrhages in typhoid fever; by the administration of opium, morphin, or the acetate of lead, should be respected for its age rather than for its logic. The effect of the opium is to dry up every secretion from the mouth to the anus, and the reduction of the bile in the intestine leads to decomposition and the formation of gases in the bowel, and to the absorption of poisonous products into the system. Tympanites, always an unfavorable symptom in typhoid fever, is especially undesirable in hemorrhage, which the distension of the ileum will be likely to renew. His practice, therefore, is to give a saline laxative to relieve all tension of the bowel, and to carry off the blood-clots, whose presence in the intestine offers to the bacteria a splendid nutrient medium. In addition he washes out the colon with ice-water. Thus the bowel is cleaned and relaxed, and put at rest, and the patient is given the best chance for recovery.

The Diagnosis of Morphin Addiction.—LETT (*Canada Lancet*, August, 1898) has found that the Bartley method of testing the urine of a patient for the determination of the morphin habit is by no means infallible. This test is as follows:

"Make suspected urine alkaline with carbonate of soda. To this add one-fourth its volume of chloroform or amylic alcohol. Shake well, allow to settle, draw off the chloroform and add a small amount of iodic acid. If morphin be present a violet tinge will be noted."

Lett has known this test to give positive results in a number of instances where there was the very best reason for believing that the persons whose urines were tested had not taken any morphin; and, furthermore, the test sometimes fails in the presence of morphin, as in the case of one patient who was taking nearly 3 grains of the drug daily. A better method is the following:

"Collect about twenty ounces (less will do) of the suspected urine. If it has not an acid reaction acidulate with dilute hydrochloric acid until it reddens blue litmus. Concentrate to about three ounces and let stand in a cool place for twelve hours, and then filter. To the filtrate add sufficient carbonate of sodium to render it alkaline, and let it stand for twelve hours, and then filter and collect the precipitate. Wash this precipitate with distilled water made slightly alkaline by carbonate of sodium and dry it. Digest the dried precipitate with pure alcohol at a gentle heat and filter, evaporating the filtrate to dryness, and dissolving the residue with dilute sulphuric acid. Test for morphin by the iodic-acid or other well-known tests for morphin salts."

By the above method Lett has succeeded in obtaining morphin sulphate from the urines of persons taking very minute amounts of the drug, and has been able to identify the crystals by means of the microscope, when the Bartley test failed.

Apenta Water in Yellow-Fever Cases.—The clerk of the Touro Infirmary, New Orleans, reports that during the recent yellow-fever invasion, Apenta water was used with gratifying success for the purpose of evacuating the bowels. Large quantities of Apenta water are said to have been forwarded through the medical supply depot United States General Hospital to Santiago, Cuba, for similar use in the Army.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, AUGUST 27, 1898.

THE MALTREATMENT OF OUR SOLDIERS TO BE THOROUGHLY INVESTIGATED: CONGRESSIONAL INQUIRY DEMANDED

Now that the war is over, we trust that the time has come to avenge the many wrongs put upon our gallant soldiers by those public servants whose cheerful duty it should have been to shield them in every possible way. In view of this sentiment, we hope that the expressed intention of ex-Postmaster Dayton to probe thoroughly the needless neglect of our soldiers will not be words writ upon the sand. He is said to have recently addressed a meeting, called to furnish aid to sick and wounded soldiers, as follows:

We are going to find the men who are responsible for the dreadful conditions that have existed. We are going to get evidence from every available source to determine the responsibility for the outrageous and shameful neglect of sick and wounded soldiers, and for the horrible condition of the transports that carried them away from Cuba. Suffering and death as the result of official incompetency will be investigated on every possible line, and the public will know where the guilt belongs when we have finished.

There will be no protection for the guilty, and neither dignity of official position nor official influence will hide the ones who are responsible. If the responsibility for this wretchedness and suffering belongs to the head of the War Department or to the head of the Administration, or to any other head, it will be known and fixed. We solicit information from every source to aid this work.

The committee appointed to conduct this investigation is headed by Augustus W. Peters, President of the Borough of Manhattan; R. B. Roosevelt, the secretary, will receive all communications. Every soldier who has suffered from neglect may send a detailed statement, accompanied by an affidavit, if possible, to Mr. Roosevelt, at Sayville, L. I., or at No. 33 Wall Street. All who know of such suffering are invited to do the same thing.

This will make a good beginning. The best ending, however, will be a full and comprehensive investigation by Congress of the crimes against our soldiers. Our representatives in Congress are not all heartless and callous politicians. The unseemly attitude assumed by certain of our Washington employees, low as well as high in rank, has been that every wrong against the soldier that has been made public and condemned, has been either a false charge or "an unavoidable circumstance;" also, that these various blunders and sins have been of minor importance as compared with the other great things that have been done, whereas, in the eyes of the public, the vastly important and supremely urgent question has been: "Have our soldiers at the front been fed and protected and cared for in every way and in every emergency as we ourselves would wish to be dealt with if we had been compelled to carry a rifle to Cuba?"

THE DUTIES OF PEACE.

THE cessation of hostilities and the declaration of an armistice has brought relief to strained nerves and anxious hearts. Grim visaged war has smoothed its wrinkled front. The stern alarms of actual battle have ceased, but the time has not come for dallying with the lascivious pleasing of the lute. To the medical and sanitary arm of the service, new problems of gigantic import loom on the Southern horizon. For the present, at least, military governments must be maintained in all the newly acquired territory. Garrisons must be established at many points, and the Augean stables of filth and infection must be cleaned. For the latter, sanitary engineers of the first rank are required, and works commensurate with the objects to be accomplished, and permanent

in character, should be undertaken without delay.

For the medical department of the army, it will suffice to see to it that the location, sanitation, and general healthfulness of the garrisons are assured. It must not be forgotten that for us as a nation, the undertaking is a new one; soldiers accustomed to the bracing air of temperate latitudes must be carefully acclimated to tropical weather with its intense heat, drenching rains, and debilitating humidity in the midst of perennial infectious and contagious diseases. Were we pioneers in this field of work, much would necessarily have to be learned in the bitter school of experience. Fortunately for us, such is not the case. England has been solving this problem in a practical way for more than a century, and to him who will lend an attentive ear has much to teach of life-saving value. It is true that the native energy, dash, and bravery of the American soldier when fresh from his native heath can drive before him any tropical fighting line he may meet. This was demonstrated in the assault upon Santiago and has been repeated at Manila, but the secondary effects are disastrous. He cannot endure exposure to the drenching rains, the baking sun by day, and the damp ground at night; nor can he, with impunity, do the digging, the pack-carrying, the camp making, and the cooking. As was pointed out in a recent editorial in the *Philadelphia Press:* "White men, the English have learned, cannot campaign in the open air during the wet season in the tropics unless they have an army of attendants. The English expedition which went to Abyssinia just thirty years ago under Lord Napier of Magdala, had 16,000 English soldiers and 32,000 native attendants to take care of them. All English tropical expeditions are organized after this fashion. Every regiment has its waterman and its tentmen, its carriers, and its cooks. The fighting man in the tropics must be taken care of. A force of laborers, all tropical, must be hired. Instead of feeding the idle at Santiago on landing, not an able-bodied man among the natives should have been given a ration unless he was willing to work, and strict military discipline should have ended the fatal and inexcusable nonsense of precious Northern fighting material courting fever and inviting death by digging and pack-carrying when idle Cubans were standing around eating United States rations.

"If this course had been followed, while fever would have come, it would not have demoralized and broken the strength and fighting force of brave men as it did at Santiago, and assuredly will at Manila. The prediction is easy to make, for it is based on two centuries of Anglo-Indian experience —the instant General Merritt's force moves from its lines and begins active operations in the field, where the men have to get wet, unless they are provided with a plentiful supply of coolies to fetch and carry and spare the white men, tropical fever will mow a broad swath through the strong ranks and a quarter will never come back.

"These are words of truth and soberness. Every medical man and every man of tropical experience or knowledge, knew that the Santiago campaign was a terrible risk. The nation deliberately matched with fever and death for victory and won in the grim game by overmastering bravery. But for white men, nothing foils tropical fever except close personal care. If a white man in the tropics has to dig and get wet and do common labor, he collapses in all cases and dies in about one-half the instances. Unless there is to be a terrible waste of life, the Anglo-Indian plan of minutely caring for white men in the tropics must be adopted in Cuba. Any other plan is sure to end like the present collapse at Santiago due to climate, doubtless aggravated by faulty staff administration, but primarily due to climate."

AUTO-INTOXICATION, PTOMAIN POISONING, AND AUTOTOXEMIA.

THE term "auto-intoxication" or "auto-infection" is best restricted to those symptoms directly referable to the action of poisonous ptomains. Chemically, ptomains are basic substances formed as a result of *putrefactive* or fermentative processes, such as *tyrotoxicon* in cheese, milk, or ice cream; from fish, *muscarin;* from poisonous mussels, *mytilatoxin.* All micro-organisms capable of giving rise to disease from poisonous ptomains within the system may, and doubtless do, produce the symptoms which are ascribed to the infectious diseases.

Ptomains may have their origin within or without the body. We are, as yet, unacquainted with the effects of those ptomains formed in the normal body by the common colon bacillus and other bacteria

which inhabit the normal intestine. This effect, whatever it may be, is "auto-intoxication."

If we should eat a piece of cheese or pork, or should we drink milk, any one of which has undergone putrefactive changes outside of the body, it could not be properly called auto-intoxication (self-poisoning), but is, in brief, *ptomain poisoning*. On the other hand, "autotoxemia" is best restricted to a diminished or an excessive amount of a normal secretion, or to poisoning by leucomains.

An excessive amount of a normal secretion will produce autotoxemia, as instanced in jaundice and salivation, and a diminished amount of a normal secretion causes autotoxemia, as is the case in myxedema. Most leucomains are wholly inert, while others are violent poisons. Of the poisonous leucomains may be mentioned paraxanthin, methylxanthin, hetroxanthin, xantho-creatinin, and gerontin. Poisonous leucomains are found in the normal secretions and excretions, such as saliva, bile, urine, perspiration, feces, and expired air.

Again, the symptoms of poisoning by ptomains and leucomains differ very widely; in the former, usually developing within the first twenty-four hours, and accompanied by nausea and vomiting, intense pains in the epigastrium, obstinate constipation, subnormal temperature, or only slightly elevated, cold perspiration, and frequently collapse and death.

Autotoxemia develops slowly with manifold symptoms referable to the muscles (as in lumbago); in the central nervous system, as evidenced by despondency, mental hebetude, insomnia, possibly epilepsy, and also in the peripheral nervous system, as observed in hemicrania, neuralgia, and possibly multiple neuritis.

The subject of bacteriology has developed within a few years to a wonderful degree, but its invariable accompaniment, autotoxemia, is still an undeveloped field to be thoroughly explored by those who study internal medicine, and who first gain some insight into the first pathological process in disease.

ECHOES AND NEWS.

Spain's Quarantine against Her Returning Troops.—The Spanish troops returning from Santiago will land at the three ports, Santander, La Coruna, and Vigo. At each of these ports, transports fitted up as hospital ships will be stationed to receive the soldiers afflicted with yellow fever.

Artificial Albumen.—Dr. Lilienfeld announces that he has been able to produce in the laboratory, by certain chemical combinations, a synthetic substance which responds to every test of albumen, and has named it artificial albumen. Whether or not this substance has the nutritive qualities of natural albumen has not yet been determined. It is announced that researches to establish this point are proceeding.

The American Microscopic Society.—The twenty-first annual meeting of this society will be held in Syracuse, N. Y., August 30, 31, and September 1, 1898. The sessions will be held in the Syracuse University Medical College, where every facility of rooms and apparatus will be put at the disposal of the Society. An interesting program, both scientific and social has been arranged. There will be reduced rates upon the railroads from any station in New York.

The Water-supply of Cities.—The average daily water-supply, as given by the New York *Sun*, of some of the large cities of the world is as follows: London, 175,000,000 gallons; Paris, 100,000,000 gallons; New York, 290,000,000 gallons; Baltimore, 70,000,000; Boston, 60,000,000 gallons; St. Louis, 55,000,000 gallons; San Francisco, 25,000,000 gallons; New Orleans, 18,000,000 gallons. There are now in New York 50,000 water-meters, and the city collects $5,000,000 per year for its water tax.

The Degree of "Doctor of Hygiene" in Great Britain.—The following colleges and universities of Great Britain hold examinations and grant diplomas in public health: London University, Cambridge University, University of Oxford, University of Durham, Victoria University, Royal College of Physicians of London, Royal College of Surgeons of England, Edinburgh University, Glasgow University, University of Aberdeen, Royal College of Surgeons of Edinburgh, Royal University of Ireland, University of Dublin, Royal College of Physicians, and Royal College of Surgeons, Ireland.—*The Health Magazine.*

General Sternberg Demands Investigation.—Surgeon-General Sternberg has written a letter to the Secretary of War formally asking for a Court of Inquiry to investigate the charges of neglect and incompetency which inflicted so much suffering upon our soldiers in Cuba. It is thought that this request of the Surgeon-General will overcome the disinclination of the President and Secretary of War to re-open at this time the controversy between the various departments. Lieutenant-Colonel Pope, chief surgeon of the Fifth Army Corps during the greater part of the campaign of Santiago, has been ordered to Washington to report to the Surgeon-General.

He Could Not Be Turned.—A patient in an English insane asylum imagined himself dead, and nothing could drive the delusion from his brain. One day the physician had a happy thought, and said to him: "Did you ever see dead man bleed?" "No," he replied. "Did you ever hear of a dead man bleeding?" "No." "Well,

if you will permit me, I will try an experiment with you, and see if you bleed or not." The patient gave his consent, the doctor whipped out his scalpel and drew a little blood. "There," he said, "you see that you bleed; that proves you are not dead." "Not at all," the patient instantly replied; "that proves that dead men can bleed." —*New York Tribune.*

Typhoid Fever at Montauk Point.—It has been decided by the Surgeon-General of the Army to transfer all typhoid-fever cases immediately upon their appearance to city hospitals. Not only can the cold-bath treatment be more consistently carried out in this way, but the sanitation of the camp can be more thoroughly maintained. Up to the present time all the cases have been transferred to the hospitals at New Haven, Conn. In accordance with this decision the ambulance ship "Relief" from Porto Rico with 248 sick and wounded, 154 of whom were typhoid-fever cases, went direct to Brooklyn and distributed her pitiful cargo among the hospitals of that borough. All these typhoid cases developed on the transports during the voyage to Porto Rico so very soon after landing showing that the infection was acquired at the home camps. The death-rate has been about double the average mortality of this disease.

Fate of the Antivaccination Bill in Parliament.—A correspondent of the MEDICAL NEWS, writing from London under date of August 10th, says: "It has been possible by coming here to follow the fate in Parliament of the Antivaccination Bill, so roundly denounced by Sir Thomas Grainger Stewart in his opening address to the British Medical Association. As at first reported to the Commons, it did not contain the objectionable "conscientious-objector" clause referred in my first letter. This permits any man swearing to his convictions before two magistrates to escape vaccination in himself and his family. It was attached, however, and the bill went to the Lords, who made a fierce fight against the clause, and defeated it by a majority of two, in spite of Lord Salisbury's strenuous plea and Lord Lister's astounding support. Back it went to the Commons, which refused to consider an amendment, and it was finally passed by dint of "packing" the Upper House, and now only awaits the royal signature, which, of course, it will have. The Lords have been roundly abused by both lay and medical press, but their stand was a weak-kneed bluff which the Government soon called. So England goes back thirty years on this point, and it will not be long before we hear of a new Gloucester epidemic, when the whole country quarantined against the town."

Suffering on Board Hospital Ships.—The intense interest of the whole country is still fixed upon the abuses and neglect attending the ambulance ships which brought the sick and wounded from Cuba. Dr. Victor C. Vaughan, who was the surgeon in charge of the Transport "Seguranca," which brought 331 sick and wounded soldiers from Siboney to Tampa, and thence to New York, declares that his experience leads him to believe that a great deal of the distress and suffering which was found upon the earlier transports, was due to the greed of the ships' captains and stewards. He believes that every transport that left Siboney had on board plenty of good food, but it belonged to the transport, and not to the Commissary Department. It was, therefore, served only to those passengers who could pay for it. Dr. Vaughan narrates that he went to the steward of the "Seguranca" and asked him for food for the men. "Not a cracker shall you have," responded the unpatriotic steward. Dr. Vaughan, therefore, took the keys away from the steward and gave them to another officer with instructions to supply the men with whatever they needed out of the ship's storeroom. He instructed the commissary to keep account of the stores used and to pay for the same at a fair valuation. Had the surgeons in charge of transports known that they had this authority, and exercised it, their passengers might have been provided equally as well as those of the "Seguranca."

Improved Ambulance System in the Borough of Brooklyn.—A member of the Department of Health explains, as follows, the present status of the Brooklyn ambulances: "In the old city of New York the Department of Charities has had full control since 1870 of public ambulances, while in old Brooklyn the Department of Health had the power. The Corporation Counsel was asked for an opinion, which was given in May, 1898, to the effect that, according to Section 1168 of the Greater New York Charter, it devolved on the Department of Health. Then the Board of Estimate was asked for an appropriation, and it immediately gave an amount equal to the emergency. The Long Island College, Brooklyn Homeopathic, St. Catherine's, Eastern District, St. Mary's, St. John's, Methodist Episcopal, and Norwegian hospitals, at which ambulances were previously stationed, were allowed, commencing July 1st, an appropriation, and the Department of Health also included in addition to the above an appropriation for an emergency ambulance at the Kings County Hospital. At Coney Island one is maintained by the department during the summer months, and if a hospital were located in that section the ambulance-service would be maintained during the entire year. The service, as far as calls are concerned, is placed, as formerly, in the hands of the Police Department. The borough is to-day fully covered by eleven ambulances, and all accidents are attended to. In the event of any ambulances being out of their own districts, the nearest ambulance to that district will respond to any call from the uncovered district."

Alleged Increase of Hydrophobia in Egypt.—According to the London *Lancet* for July 23d, in the early days of the British occupation there were thousands of pariah dogs in Cairo, and it used to be said on all sides that rabies was unknown, but in 1886 a fox terrier at Abbassiyeh belonging to a British soldier broke the record by being the first case. Since that time, every year cases among human beings or among dogs have been reported and verified. Besides many doubtful cases the whole number up to last month comprises 36 dogs, 2 wolves, 3 horses, 2 mules, and 60 human beings, all fatal, scattered over

Egypt. Since 1893, several bitten people have gone to Paris or to Athens to be treated, and this year already 9 persons out of 15 bitten have gone to the Athens Institute. These figures are enough to show that preventive measures are required. Though there are no medical accounts of rabies in times past there are plenty of supposed cures which make it appear as if the disease were well known. Papyri contain mention of the dangers of a bite from serpent, crocodile, or dog. Charms were sold in old days to protect from these three, and there is a folk-lore story in which the wicked fairy condemned the heir at his birth to be killed by one of these three biting creatures. He destroyed a serpent which attacked him, and he and his favorite hound killed a crocodile, but the master died in consequence of an accidental bite from the dog during the fight. The modern treatment for a person bitten by a presumably mad dog in Upper Egypt is to kill the dog, extract the spinal cord, bruise the cord with pestle and mortar until a paste is made, and then to rub the patient's body with the paste. Sometimes, too, they burn the dog's hair and apply the ashes to the bite. The Bedouin make the patient eat the raw liver of the dog, and this is done, too, in the Haussa State of the Western Soudan. In Lower Egypt the favorite remedy has been acquired from the Syrians of Mount Lebanon. It is the Mylabris punctata, a dark-blue beetle used instead of cantharides, and well known in the south of France and Spain.

Service of the Pasteur Institute at Rio de Janeiro.—From April 9th, the date on which in Brazil the prophylactic treatment against hydrophobia was commenced, up to June 30, 1898, 4068 persons have applied for the assistance of the Pasteur Institute, here existing under the direction of Professor Dr. Ferreira dos Santos. Of that number, 2695 persons have been treated, 172 last year. Treatment has been refused to the persons bitten when it was discovered that the animals were not suffering from lyssa. In two instances it was subsequently discovered that persons rejected on the plea of not having been bitten by rabid animals had actually been so bitten, having shown symptoms of hydrophobia. Three other patient were rejected because they had already been attacked by lyssa when they applied for prophylactic vaccinations. Of the 2695 persons treated, 1935 had been bitten on uncovered parts of the body, and 760 through the clothing. Application was made in 10 instances by employees of the Institute on account of accidents occurring during experiments with animals; in three instances sores, resulting from other causes, have been contaminated by contact with the saliva of affected persons, and in two instances the patients have been bitten by persons suffering from hydrophobia. As for the rest, the wounds were caused in 2383 instances by dogs, in 287 instances by cats, in two instances by mules, in one by a cow, in two instances by asses, in one by a horse, and in four instances by monkeys, In 237 animals the existence of rabies was shown by the experiments; 1196 animals showed undoubted symptoms, and 1292 animals highly suspicious symptoms of the disease. The number of persons who did not await the termination of the treatment, and that of those in whose cases it was discovered that the animals by which they had been bitten were not suffering from rabies was 99. Among those included in the former class there were three who are known to have been taken with hydrophobia after leaving the Institute. In six cases of patients under treatment the lyssa made its appearance before termination of the treatment. During the treatment five patients died of other diseases. Of the 2585 persons treated, twenty died from hydrophobia, the mortality resulting from this disease being consequently .77 per cent. In these twenty cases hydrophobia appeared in nine instances within fifteen days after the treatment had been completed. Before the announcement of Pasteur's discovery the mortality from rabies, according to Leblanc, had been sixteen per cent. One thousand five hundred and forty-five persons treated were residents of the city of Rio de Janeiro; the others came from different parts of Brazil.—W. HAVELBURG, M.D., Acting Sanitary Inspector U. S. M. H. S.

CORRESPONDENCE.

THE INCOMPETENCY OF THE WAR DEPARTMENT.

To the Editor of the MEDICAL NEWS.

DEAR SIR: The bungling mismanagement and inefficient supervision of the office of the Secretary of War in the transportation of the Army of the United States to Santiago, Cuba, the promiscuous appointment of political loggerheads to staffs in the commissary and quartermaster departments, the mismanagement and delay in transporting the necessary field-hospital requisitions which necessitated so much horrible suffering of the wounded of our army after the battles at Siboney and Santiago, and the utter neglect to supply our worthy and courageous soldiers (for two days) with even a bite of food, together with the last and most horrible cruelty meted to the suffering wounded in overcrowding the returning transports with sick and wounded, and the neglect to furnish the necessary medical supplies for the relief of their sufferings, as stated by your correspondent in the MEDICAL NEWS of August 6th, calls for more than mere comment and investigation as per your editorial in same issue. Such inhumanity calls for more than a protest. I believe all medical men who read said article will rise united as one man and demand that a more capable officer should be at the head of the office of the War Department of these United States. I believe that to do our duty we should at least petition to our most capable Chief Magistrate, the President of the United States, requesting the resignation of the present incapable incumbent of the office of the War Department. In doing this I believe we express the sentiment of the whole people. I would further request that every medical journal take this matter to issue, and spread it broadcast that other nations may not judge the people of these United States wrongly. Very sincerely yours,

W. H. DUKEMAN, M.D.

LOS ANGELES, CAL., August 11, 1898.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

AN OLD MEDICAL JOURNAL—VIRCHOW'S MEDICAL REFORM AND SOME NEW ONES—PROFESSOR WALDEYER ON SEXUAL DIFFERENCES IN FETAL BRAINS—NO POLISH SCIENTIFIC CONGRESS TO BE HELD AT POSEN THIS YEAR—THE MEETING IN 1900 AT CRACOW—VIRCHOW ON SYPHILITIC LESIONS OF THE INTESTINES AND SO-CALLED SYPHILITIC ULCERATIONS OF THE RECTUM.

BERLIN, August 16, 1898.

JUST fifty years ago last month Virchow and Leubuscher began the publication of a weekly medical journal, *Medicinal Reform*, which though it lasted but a year, represents a landmark in modern medicine. It was the stormy times of '48, and the spirit of revolution was abroad. More than one European monarch had gone down before that contagious spirit of uprising that spread over Europe, as never epidemic had spread before. German thinkers were aroused, German politicians were at work on a scheme of union for Germany. German philosophers were theorizing in charmingly impractical fashion on the rights of man and reform. Reform was in the air. Virchow established the journal for the purpose of uniting medical men in a scheme for the reform of the laws regulating their positions as doctors. A good deal was accomplished; much was still wanting, but the time was not ripe. Some of the abuses that were then pointed out in the laws relating to physicians still exist, and are the subjects of negotiation between the medical societies and the authorities to-day.

After awhile came Virchow's call to Wurzburg, and with that the stoppage of the journal. Many of the earlier numbers was written by him personally, and nothing better on such subjects as the government's duty in the matter of public health has been written down to our own day. The duties of the government in the matter are stated with a clearness and precision all the more surprising, as the subject was a comparatively new one, in the extent to which Virchow would apply its principles, that they are to-day generally accepted opinions. One of the contributors to the early numbers was Traube, and the subject was the "Advantages and Disadvantages of Special Clinics." A view of another knotty problem is this, to which very little could be added in our day, though the subject has become a very vitally interesting one for us.

One of Leubuscher's articles at the beginning of the volume was on "Medicinal Pfuscherie" (Medical Quackery). Another of Traube's articles is "Shall the Directors of Hospitals and Clinical Teachers Be Allowed Only a Consultation Practice?" questions which would be of interest in our day, and which much more ambitious weekly journals than this little one (whose first number consisted of four quarto pages containing one advertisement), would be very ready to receive into their columns.

It is a little discouraging to think that the great advances of the last fifty years have carried us not much farther toward the solution of these great questions of medical rights and privileges than medical men were then. Virchow's appeal for union and cooperation in the common cause would be as opportune almost to-day as it was in that transition period of '48. Virchow reminded the doctors of that period that it availed nothing to belong to a great profession, if the rights and privileges of that profession were not upheld by the concerted action of its members. *Paullum sepultæ distat inertiæ celata virtus.* Merit hidden under a bushel, might as well be helpless inactivity.

July, as the mid-year, has seen the first appearance of a number of brand new German medical journals, of which the most prominent are the *Journal of Dietetics*, of which Professors Von Leyden and Goldscherder of Berlin are the editors, and *Beiträge für Geburtshilfe und Gynækologie*, of which Professor Hegar of Freidburg is the editor. Two new journals are announced to appear later, a *Jahresbericht in der Gebiete der Neurologie*, to be issued in January next with Professor Mendel of Berlin as editor, and a *Vierteljährschrift für Kriminal Anthropologie und Kriminalistik* with Dr. Hans Gross of Leipzig as editor, and a number of prominent criminal anthropologists as collaborators. This last journal takes the place of the one that I mentioned some time ago in these columns, as having ceased publication because its editor had been giving his distinguished collaborators some practical lessons in criminal anthropology. He is at present enjoying unrivalled opportunities to study criminalistics in one of the large German prisons at the expense of the State, the conviction having been for swindling. His collaborators gained some unique experience in practical dealing with ingenious criminals. That he was something of a genius may be gathered from the fact that he should have recognized a new field in German medical journalism (not an easy thing in the present crowding of the medical printing world) which others find it expedient to occupy, now that his enforced retirement (for reasons of State) leaves the opportunity open.

Professor Waldeyer presented at a recent meeting of the Berlin Anthropological Society two pairs of fetal brains in which the conditions as to weight and age were so alike that some conclusion as to the absolute comparison between the development of the brains of the different sexes seemed to be justified. In the first pair the male fetus was .264 meters long, weighed 362 grams and the brain weighed 32 grams. The female was .256 meters in length, weighed 850 grams and the brain weighed 30 grams. In the second pair the male fetus was .400 meters long, weight 1185 grams, brain weight 175 grams; female .400 meters long, weight 1188 grams, brain weight 165 grams.

Professor Waldeyer has reported somewhat similar conditions before, and though the number of observations so far made are scarcely sufficient to justify a definite conclusion, yet he considers them to have certain manifest indications as to the comparative brain value of the two sexes at a time when education and training has not yet come in to vitiate conclusions. With fetuses practically the same size and weight there is distinctly more brain substance in the male than the female. This

is very striking in the second case where the female fetus is actually slightly heavier, and where, besides, the brain convolutions were somewhat farther developed than in the male. Professor Waldeyer asks for the sending of fetal brains or the careful observation of them by others in this direction, as of course the opportunities for such observations are extremely rare.

As the prohibition by the Prussian police department of the attendance of foreigners at the Polish Congress of Naturalists and Medical men would have made serious lacunæ in the program of the congress, it was decided not to hold it at all this year, as I mentioned in my last letter. The next meeting will be held at Cracow in 1900, during the fêtes in honor of the five-hundredth anniversary of the foundation of the University of Cracow. For the moment the Prussian Government has secured its object and prevented the assemblage of the Slavs in Germany. Whether this interference with a scientific congress will not have a greater effect on reactionary Slavish sentiment than anything the proceedings of the congress might have been able to effect remains to be seen.

Meantime there is as good as an official announcement of the fact that the United Slavs, Czechs, Poles, and Russians are going to make the meeting in 1900 memorable. They have, of course, an inspiring occasion, the half-millennial celebration of one of the oldest universities in Europe, whose fame was at one time world wide. No pains are to be spared to show the world what the Slavs have accomplished in the past, and despite unfavorable conditions, are accomplishing at present, in science and the arts of education.

Professor Virchow has been lecturing on the pathology of the intestines on Saturday during the semester, and at one of the final lectures of the year came to the subject of syphilitic lesions. His main attention was directed to the series of lesions ulcerative in character and leading to stricture of the rectum, which are usually set down as syphilitic in origin. Some few of these, he thinks, may be caused by syphilis, since they have most of the pathological characters of the disease, but most of those usually pronounced syphilitic clinically and even on the post-mortem table are not, but are due to an obscure pathological process or series of processes, whose explanation will constitute a distinct advance in the pathology of the intestines.

Notwithstanding his immense experience with post-mortem specimens Virchow has never seen a gumma (or rather, as he insists gummi, since there is no such Greek word as gumma) of the intestines. He does not, therefore, deny that gummata of the intestine occur, but thinks they must be extremely rare. It would be in a gummatous process that these ulcerative strictures of the rectum would occur if they were really syphilitic, but they are entirely too frequent for that. Besides their almost exclusive limitation to women point to the fact that there is something more than a syphilitic process at work. This opinion that these so-called syphilitic strictures are not such is gaining ground. Professor Wölfler, at Prague, thinks that the number of them attributed to syphilis is far above what it should be, and Professor König, here at Berlin, says that to his mind they are due to a mixed infection after gonorrhea of the rectum, occurring so frequently in women because gonorrheal secretion finds its way so easily over the perineum to infect the mucous membrane at the anus.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

Sixty-sixth Annual Meeting, Held at Edinburgh, July 26, 27, 28, and 29, 1898.

[Specially Reported for the MEDICAL NEWS.]

(Continued from page 255.)

SECTION ON SURGERY.

SECOND DAY—JULY 28TH.

DR. DAVID NEWMAN of Glasgow opened the subject of the treatment of

SEPTIC INFECTION OF THE URINARY TRACT,

confining his remarks to the kidney. Renal sepsis may arise from the blood- or lymph-streams or there may be "acute septic nephritis without suppuration," infection taking place usually from the ureter. The bladder is not easily rendered septic but once infected, the distribution of the lymph-supply spreading to the kidney is not difficult, and may occur without the intermediary of the ureter. The chief point in treatment is prophylaxis.

DR. ROVING of Copenhagen stated that two groups of bacteria affect the passages, those which decompose urea, pus-cocci, other diplococci, and bacilli, some non-pathogenetic, and those which do not decompose urea, such as the bacillus coli. In bacteruria with no cystitis, the bacillus coli occurs; when cystitis appears, it is due to the first class, staphylococci. Prevention is the chief safeguard. DR. MELCHIOR of Copenhagen read a report of fifty cases of infection in which the colon bacillus was by far the most frequent microbe found. In most cases it is introduced by instruments. MR. BRUCE CLARK held that there must be an abrasion of the mucous membrane in order to permit entrance of bacteria. Cocci first appear and these are later replaced by the bacillus coli.

DR. MELCHIOR reported the case of a girl on whom he operated for a large sarcoma of the neck. Finding it impossible to remove the growth, he used repeated applications of electrolysis (500 milliamperes for 5 minutes under anesthesia). The whole growth sloughed away and had not returned.

THIRD DAY—JULY 29TH.

DR. ROVSING of Copenhagen opened the proceedings with a paper on

OBSCURE HEMORRHAGE FROM THE KIDNEY AND ITS TREATMENT BY NEPHROTOMY.

He began with a description of several cases of bleeding from one kidney as shown by the cystoscope, for which there was no assignable reason. In two of them the bacillus coli was found in the urine, but the speaker thought this organism held no etiological relationship to

the diseased condition. It is possible that displacement of the kidney may have had something to do with the bleeding by reason of venous engorgement. In two of his cases he practised nephrotomy with good results so far as cessation of hemorrhage was concerned.

MR. PARRY of Glasgow in speaking of

SPASMODIC TORTICOLLIS

described three cases in which the deformity was persistent and due to spasm of the muscles, not their permanent contraction. He cured all the patients by resecting a portion of the spinal accessory nerve on one side and severing the cervical plexus on the other, thus removing the spasm of one sternomastoid and the opposite occipital muscle. No paralysis resulted.

MR. NOBLE SMITH of London had treated sixteen cases in this way and regarded the operation as well established, but DR. KOCHER of Berne said that he had often seen recurrence. He now divides the sternomastoid on one side and the occipital muscles on the other.

MR. JONATHAN HUTCHINSON, JR., of London gave an account of a case of

TRIGEMINAL NEURALGIA TREATED BY REMOVAL OF THE GASSERIAN GANGLION.

There are two routes of approach to the ganglion: (1) By resecting temporarily the zygomatic arch and trephining about the foramen ovale; (2) by trephining the squamous plate and lifting the temporal lobe without injuring the dura. It is not necessary to ligate the middle meningeal artery. The temporal route is the operation of choice since it is attended by less risk and less deformity.

MR. ROBSON of Leeds preferred the second method, thinking a beneficial effect may be secured by forcible stretching of the third branch of the trigeminus.

DR. BRUCE of Dingwall, in speaking of

SCIATICA,

claimed that it is always due to disease of the hip-joint, occurring especially in those with uric-acid diathesis. His treatment is directed along this line.

DR. KENNEDY of Glasgow presented notes of cases of

TRAUMATIC MUSCULOSPIRAL PARALYSIS FOLLOWING FRACTURE OF THE HUMERUS.

Improvement ensued in every case after freeing the nerve. Delayed return of muscular power in certain instances may be attributed to the muscles rather than the nerves.

MR. MUIRHEAD LITTLE, treating of

COXA VARA,

described two varieties, one in children caused by rickets and the other in young persons produced by carrying heavy weights. The X-rays are of material assistance in making a diagnosis. The best treatment is subtrochanteric osteotomy.

The paper by ADAMI of Montreal on the

BACTERIOLOGY OF PROGRESSIVE CIRRHOSIS,

deserves a more extended notice than was given in a previous letter. In it, he says that in a large number of cases of the disease in man there may be found largely within the liver-cells, and in the lymph-spaces in the new formed connective tissue a peculiar, minute form of micro-organism presenting on proper staining the form of diplococcus surrounded by a faint halo; on deeply staining a rather obscure ovoid body little distinguishable from tissue detritus. In infective cirrhosis in cattle, the same organism is present in the tissues and shows the same staining characters. He has, moreover, been able to isolate the organism from the liver, bile, and lymph-glands of at least thirty infected cattle, and it is polymorphous, appearing as a small diplococcus when grown on broth, and as a distinctly bacillary form on solid media. The organism is pathogenic for laboratory animals, and in them is seen in the hepatic cells and elsewhere. In a case of atrophic cirrhosis in man he has been able to isolate from different organs a micro-organism with similar cultural characteristics. This discovery, if confirmed, as the author says, put a new phase on the study of hepatic cirrhosis. We get satisfactory explanations of the splenic enlargement and the frequent right-sided pleurisy, and we may be on a fair road to explain why ascites occurs in one case and in another, jaundice, depending on whether the organism sets up a peritonitis or attacks the bile-ducts and liver-cells. Adami does not believe that it causes cirrhosis only; it may be found to excite other disturbances in the liver and elsewhere, indeed to be capable of setting up a septicemic condition.

SECTION ON MEDICINE.

SECOND DAY—JULY 28TH.

Consideration of the

OPEN-AIR TREATMENT OF PHTHISIS

was continued from the Wednesday to the Thursday session on account of the inadequacy of the discussion. Following DR. DAVIDSON'S paper upon

SOUTHERN CALIFORNIA

as a resort for consumptives, the subject was taken up by DR. CALDWELL of Belfast who thought this treatment might be both preventive and curative. The former is not sufficiently practised. There is no specific drug, but the open-air method, if carried out, produces good results unless the cases at the outset have advanced too far. The treatment, which must be thoroughly carried out or not at all and away from friends, consists of continuously living in the open air, day and night, great attention to diet and exercise regulated to the patient's physical powers. DR. GUILLEMARD stated that the winter climate in the uplands of South Africa is perfect and treatment very satisfactory. DR. SIDNEY JONES of New South Wales confirmed these assertions and called attention to the fact that both in Australia and Africa, the climate varies greatly in different parts and must be considered in the choice of locations. DR. THORNE of London recited the case of a woman advanced in phthisis who, unable to go abroad, took the treatment as far as possible in the gardens of the metropolis and recovered. Other similar experiences were reported.

SIR WILLIAM BROADBENT in opening the question of the

SIGNIFICANCE AND CONSEQUENCES OF DIFFERENT STATES OF VASCULAR TENSION, WITH THEIR MANAGEMENT

limited his remarks to arterial tension. Vascular tension depends upon the force and quantity of blood delivered at each systole and on peripheral resistance. The pulse is the guide and four points should be noted regarding it: (1) the size of the vessel; (2) its states between beats; (3) the character of the rise of each stroke, and (4) the force required to obliterate it. Low tension is often found in long-lived persons, but it is found in fever and may be the cause of lessened nutrition. It is associated with debility, neurasthenia, and often with epilepsy. High tension often runs in families and may be seen in young persons. Among its effects are hypertrophy and dilatation of the heart, thickening and atheroma of the aorta and valves. Variations of vascular pressure are of universal application in all forms of disease and furnish important therapeutic indications, *e.g.*, the blue pill in neurasthenia with high tension. Convulsions occur in many high-pressure states, but they are not necessarily the result of the tension, as in uremia. In epilepsy when the tension is low the prognosis is less favorable. As regards Cheyne-Stokes' respiration it always occurs with high tension.

When instituting treatment, the essential origin must be learned. In low tension it may be some vice of nutrition, digestive derangement or absence of glandular secretion, especially the suprarenal. The most useful drugs are eliminatives, digitalis, and caffein. In high tension, the chief cause is toxemia. Diaphoretics, baths, exercise, diuretics, and purgatives are indicated and most importance is attached to mercury, the old contraindication in uremia being now exploded.

Professor Bradbury of Cambridge said that treatment of low tension is treatment of its cause, which is found outside the vessels; palpitation of nervous origin is the chief symptom. High tension is dependent on vascular or cardiac conditions, and is important in its causal relations to disease. Poisons, syphilis, gout, lead, cause contraction and produce the pressure. Much may be done to alleviate the condition; in fact, improvement may always be looked for. The essential object is elimination of toxic substances and prevention of their reaccumulation. Potassium iodid and purgatives are useful but not in emergency when vasodilators, nitroglycerin, amyl nitrate, erythrol, tetranitrate may be used.

Dr. Savill drew attention to an important sequence of high tension, *viz.*, arterial thickening, which he calls "arterial hypermyotrophy." He found it in fourteen per cent. of necropsies. The change is a true hypertrophy but may be accompanied by pathological alterations. Dr. Haig thought the time had come when the right name should be given to the toxin of high tension. It is uric acid.

Dr. Drummond of Newcastle read a paper on

ETHER PNEUMONIA,

in which he said that cases of death after operation are often attributed to sepsis when they were really due to this condition. He narrated a fatal case, necropsy showing engorgement and edema of the lung. Pulmonary disease predisposes and it is especially apt to occur after abdominal operations.

Section on Diseases of Children.

First Day—July 27th.

Dr. Joseph Bell of Edinburgh, President of the Section, opened the proceedings with some preliminary remarks, welcoming the members of the section to Edinburgh. In a general way he deprecated the too general custom of sending sick children into hospitals to the exclusion of home-treatment. The very poor who have dirty homes and who starve their children, may have a sort of reason when they bring their children to light, water, and food; but the great middle class should be reminded of their responsibilities. A large number of operations which crowd the hospital work should be done at home. Mastoid cases, tuberculous glands and joints, radical cures of hernia, phimosis, need not be taken to hospitals for proper treatment. If the child cannot be made aseptic in a decent home, the surgeon is not up to his work.

A discussion upon the

TREATMENT OF SPINAL CARIES

was opened by Dr. Victor Horsley. The author devoted his paper more especially to the subject of tuberculous osteitis as a cause of deformity, and its treatment. Early operation is indicated in these cases. The diseased bone should be freely removed and free drainage insured by laminectomy and, when necessary, removal of the pedicles. This must be followed by temporary fixation to prevent deformity. This is secured by elastic extension. Dr. Robert Jones of Liverpool deprecated too early operation. Elastic extension when strong enough to extend the spine is, as a rule, intolerable to children. Early cases can be effectively treated by placing them in a recumbent posture with the back in lordosis, the spine being supported in this position and the hips resting comfortably. The lordosis must be maintained to a certain degree by apparatus when the patient assumes the upright posture. He reported ninety-four cases of immediate reduction. Dr. Murray of Liverpool opposed the immediate reduction of deformity in these cases. Application of that treatment in fourteen cases had been unsuccessful, deformity recurring in all. Dr. Tubby of London reported thirty cases in which immediate reduction of deformity had been applied by him with the result that four spines had been permanently straightened and the majority of the other cases greatly improved. Dr. Noble Smith of London disapproved of taking away the pedicle and laminæ which, in these cases, were frequently the only sound parts of the vertebræ, but thought it advisable to remove diseased bone when it could be easily reached. Dr. Churchill of London and Dr. Luckham of Salisbury advocated expectant treatment and good hygiene. The remainder of the session was spent in the discussion of surgical subjects as follows: The treatment of club-foot, hare-lip, cleft palate, dislocation of the hip-joint, occurring in the course of infectious diseases, and the clearing out of the mastoid antrum in infants and young children.

SECOND DAY—JULY 28TH.

MR. JONATHAN HUTCHINSON opened the discussion on

CERTAIN ASPECTS OF CONGENITAL SYPHILIS.

He discussed certain late manifestations, especially lesions of the bones and organs of special sense, and insisted that these were very rare after the age of twenty. The diagnosis of these cases involves great difficulty. The usual routine drug treatment of the disease in infants is useless. DR. H. ASHBY of Manchester discussed certain cases of doubtful character, involving lesions of the brain and other internal organs. Such cases were those of certain forms of anemia, enlarged spleen, hydrocephalus, and other conditions affecting the nervous system.

THIRD DAY—JULY 29TH.

DR. D. B. LEES of London opened the discussion on

RHEUMATIC HEART DISEASE IN CHILDREN.

The great mortality of this disease among children is in striking contrast to the same condition in adults. Dilatation is usually present in subacute, first attacks, even when pyrexia is slight and arthritis is not present. Effusion into the pericardium and endocarditis are not usually the causes of fatality. Indeed, these conditions seem to affect the mortality very little. Plastic pericarditis and dilatation, however, play a very important part in the fatal results. DR. OSLER of Baltimore, continuing the discussion, thought it very important to guard against repeated attacks of rheumatism. DR. EWART of London showed diagrams illustrating the point that in dilatation fluid was always present and emphasized the importance, from a diagnostic standpoint, of spinal dulness.

SECTION ON PSYCHOLOGY.

FIRST DAY—JULY 27TH.

The President, DR. T. S. CLOUSTON, opened the proceedings with an address on

NEUROSES AND PSYCHOSES OF DECADENCE.

A large number of the neuroses of decadence may be looked upon as premature senility and nervous death before its allotted time. Man's normal average life may be divided into three periods of twenty-five years each. During the first quarter of the century his body is growing and his functions maturing, the last organ to attain psychological perfection being the brain. During the second period, the fullest muscular action and the highest resistive power against disease, and the most reliable and intense mentalization are found. During the last period, a slow process of retrogression and decay sets in and goes on until the psychologic ending of death is reached. As during development one organ or function may lag behind its normal maturation time in reaching perfection, thus constituting a neurosis from unrelational development, so during decadence premature decay in individual organs and functions may occur, constituting neuroses through unrelational decadence. One man's trophic energy fails at fifty-five. He then loses three stone of flesh and falls a victim to the first severe bronchial catarrh that attacks him. The cardiac innervation of another fails at sixty and influenza cuts him off. The memory of another quite gives way at sixty-six, while another loses original volitional power at seventy, so that he cannot manage the simplest business.

The cessation of the great reproductive energy at the climacteric period in both sexes is attended by such frequent nervous and mental disturbances that in their lesser degrees they are commonly regarded as normal rather than abnormal in their character. During the barren period which follows the climacteric, which is a period of decadence, the human animal becomes subject to many diseases and defects that are incidental to this period. The last epoch of all, that of vascular disease, nerve-cell, and fiber degeneration, is one necessarily attended by many neuroses and psychoses. Then it is that senile endarteritis, fatty vessels, atrophies, softenings, and senile diminution come on.

The life history of the neuron and the sheathed nerve-fiber in their stages of growth, development, and decadence, histologically and functionally, has yet to be written. The very important part of such life history would be the account of the degrees of their reaction to different stimuli and susceptibility and power of resistance to the causes of different kinds of diseases at different ages and under different conditions. The effects of stimuli, and of poison, on the nutrition as well as on the kinesia of nerve-cells are certainly different at different ages of life. Sudden loud noises, or the excess of oxygen carried by blood at temperatures over 100 degrees, send many young children into convulsions but will have no effect upon boys of ten. The pychoses we lump together under the name of delirium, which is easily produced in childhood by temperature or by nerve-toxins circulating in the blood, but it is not so readily produced in the later period of life by the same causes. On the other hand, the nerve degenerations and more severe disturbances of function are far more apt to be set up in the senile periods of life by alcohol and other nerve-toxins than in early life. Such changes of structure or of function as occur in the natural growth, development or decadence of the neuron or sheathed nerve-fiber, cannot properly be maintained as disease. The imperfect observation, attention, and reasoning of the child of three is no psychosis any more than its difficult equilibration at eighteen months is a motor neurosis. So the weakened memory and the lessened force, origination, and volition of the man of eighty is no psychosis, nor do his less firm grip of the ground and his uncrisp articulation constitute motor nervous diseases. The wondrous and mysterious process of innate progression of structure and function whereby the neuron gradually acquires the capacity of exhibiting the energies we call coordinated motion, sensation, and mentalization, certainly depends on a hereditary potentiality within it together with favorable conditions of environment. If this potentiality is in any way faulty, we know that the organism is apt to suffer from the developmental neuroses in various forms. The process of decadence also implies a potentiality to be carried out in natural and physiologic fashion.

Though bad heredity does not come in so powerfully in decadence as at development, it does operate in some cases and thereby brings on decadence or disease before its time. Operate it must, for all the recent investigations into the conditions that conduce toward centenarianism and prolonged life point to heredity as being by far the most powerful cause. The answer to the question, How to live long? seems to be, Have an ancestry that did so; but I think heredity operates in a different way in decadence from what it does during development. In the one case, it is the sword that smites the potentially unfit and so stops the reproduction of the bad stock; it is Nature's chief means of weeding out the organisms that do not make the physiologic ideal she sets up in all species; it is then an actively destructive force, but in the period of decadence bad heredity is more like the weakening of the supports and roots that keep a full-grown tree from being blown over by the storms to which it is exposed from without. A tree in a sheltered spot, though spindly and not well rooted, may live long, so a man with a nervous heredity, if he has come safely through childhood and adolescence, may, with care and obedience to Nature's laws, live to a good old age; but if he drinks too much, or carries with him an old syphilis gland, or has to work too hard, or has occasion to worry much, he has not the staying power to resist such things. With a bad heredity in his nerve-centers he falls a victim to general paralysis, locomotor ataxia, brain-softenings, climateric melancholia, or senile dementia during decadence. The functional nervous explosions of convulsions are the most deadly of the developmental neuroses; the organic vascular-neurotic destructive lesions of brain-softenings and apoplexy kill most frequently after fifty.

We shall not be able to put on a really scientific basis the diseases of decadence until we know the exact steps in the normal process of decay of structure and function in every tissue and organ. The actual number of neuroses in any given field of the microscope during the senile period of life is fewer than in youth, such as is seen in brain sections from dementia. We know also that mentally their functions have lost much in quality and intensity. Different men decay mentally in different ways, but taking the majority the process begins at the memory of names and things that have no associated ideas, the mere labels and tickets that have no descriptive meaning. Place names and personal names are examples. Then there comes a diminution of the affective faculties, with a lowered intensity of poetic and idealized images, and also of things and of feelings. This, no doubt, accompanies a lessened sexual and reproductive energy. What is the latest age at which a man or woman can really "fall in love?" would be a proper and very interesting psycologic inquiry. Then comes a time when mental energizing generally gets slacker, when originality and spontaneity cease to be all powerful. The reasoning faculty weakens at a later period still. The highest of all departments of mind, the self-control, the volition, the mental inhibition generally, with the moral faculties, suffer as real senility advances. Emotionalism, irritability, lack of perseverance in action, and even immorality in speech and action are then met with. Every one of these steps in mental decadence must be correlated to physical alterations in the neuron. The old man's gait and speech both show lack of output in the motor cortical areas and lack of fine coordination of muscles. The whole body shrinks in volume except the less organized fat-cells in some cases.

I have known cases with a bad neurotic heredity, in which men had drunk hard in youth, but with apparent impunity, and stopped drinking when about forty, yet after fifty have passed into an alcoholic dementia. No doubt the cortical tissues resisted the toxic effects till decadence set in and then a something destructive from the old alcoholic poisoning killed off their higher energizing. I have known many cases where men have acquired syphilis in youth or middle life, and its germs have laid absolutely harmless in their brain cortices till they begin to turn the corner of life, when the resistance of the tissues becoming weakened, they became insane or paralyzed, or developed various forms of ataxia or aneurisms. It is well-known that plumbism is more common in men of fifty or sixty than between twenty-five and forty.

It cannot be doubted that the brain-tissues regulate by innumerable vasomotor centers their own blood-supply; and there can be as little doubt that the nutrition of other walls is also regulated from centers in the brain. No doubt in most cases of apoplexy from vascular disease, there is also some amount of surrounding nerve degeneration. There is a solidarity throughout the whole brain through which a tissue change seldom occurs in one organ, or system, or center, or envelop without some amount of pathologic change in some or most of the others.

An elaborate discussion then followed on

SUICIDE IN ITS PSYCHOLOGIC AND SOCIAL ASPECTS,

by the reading of several papers, followed by general discussion. A number of papers were also read upon the "Therapeutic Effect of Thyroid Extract."

Section on Neurology.

The scientific work was begun by Professor Ferrier, who, in an elaborate paper, opened the discussion on the

PALLIATIVE TREATMENT OF CEREBRAL TUMORS.

It is not necessary to enlarge upon the general dangers of cerebral tumors, but the specific effects that each indidividual cerebral tumor produces is always of interest and serves more and more to assist in their localization. He then gave a brief sketch of the progress of cerebral localization during the last fifteen years. This progress had enabled surgeons to operate at the present time upon subjects in whom operation was hardly permissible not many years ago. Aseptic surgery has also broadened the field of the surgical treatment of tumors of the brain. There still remains, however, one class of tumors upon which operation is not permissible, *viz.*: those at the base of the brain. In certain cases, however, it is quite permissible to give the patient the benefit of certain medicinal remedies before resorting to operative procedure.

Dr. Dercum of Philadelphia, in the discussion which

followed, advocated the use of potassium iodid in inoperable cases as a palliative measure, especially in glioma. In his hands, oxytuberculin, which he has tried in a number of cases and in which he had pushed the treatment to its fullest application, had absolutely failed. DR. JOSEPH COLLINS of New York congratulated PROFESSOR FERRIER upon the excellent success of his treatment and pointed out the fact that his statistics show twice the percentage of cures obtained by other operators and discussed the efficacy of potassium iodid as a palliative measure. A general discussion then followed, in which the treatment of headache and vomiting, which usually accompany cerebral tumors, was presented; also, the question of operation in tuberculous growths.

SECTION ON PHARMACOLOGY AND THERAPEUTICS.

FIRST DAY—JULY 27TH.

The president of the Section, DR. J. O. AFFLECK, opened the proceedings by an address on the

PROGRESS OF THERAPEUTICS.

He did not propose answering the celebrated question of the great Scottish philosopher, Sir William Hamilton, "Has the practice of medicine made a single step since Hippocrates?" for that had been satisfactorily answered by the lamented Warburton Begbie at the last meeting of the Association at Edinburgh in 1875. Since that time the number of new remedies has been multiplied enormously, chiefly by the adoption as therapeutic agents of substances which organic chemistry has so richly provided, the virtues of many of which are beyond all doubt. An illustrative instance might be cited in the power of salicin, and salicylic acid and its compounds, to lessen the pain, and in many cases, to shorten the attacks of acute rheumatism. The groups, too, of synthetic analgesics, antipyretics, and antiseptics have furnished us with substances which, while requiring at all times care and judgment in their selection and administration, are among the most widely employed and efficacious of the resources for treatment placed in the physician's power. A therapeutic measure of eminence is the method of treating stomach disorders by lavage, a plan which owes its origin to Professor Kussmaul. An entirely new field of therapeutics has been opened up by antiseptic surgery. The employment of various forms of baths is now gaining much wider and more practical recognition, and the application of regulated exercise in the treatment of heart disease by the Oertel system, or by the more recent Nauheim method, has been found to yield excellent results in many conditions of cardiac enfeeblement with or without valvular disease. The discovery that the introduction of fresh thyroid into the system of a myxedematous patient is followed by the rapid disappearance of all the symptoms, may justly be regarded as one of the greatest triumphs of modern times, while it has opened up a field for further effort in similar directions which is being assiduously cultivated. Of no less importance and with a still wider range of beneficent results, are the means which bacteriological investigation has placed within our power of identifying specific organisms in infectious diseases and observing their life-history and toxic properties. The way has thus been opened for the scientific study of immunity and this again has resulted in the discovery of protective and curative antitoxins, of which that of diphtheria is the most outstanding example. The testimony which has been borne to the value of this treatment in that dreaded malady has been universal.

The beneficent work of nurses is universally recognized and appreciated by the public as well as the profession, and is happily now made available for the poorest of the poor.

It is not too much to assume that the generation that ends with the century now closing marks an era in therapeutic progress not witnessed in any corresponding period during its course, if, indeed, ever before. It can scarcely be doubted that thereby the average of life has been lengthened, and it is certain that the pains and miseries of disease and death have been wonderfully lightened.

A discussion upon the treatment of

DISEASES OF THE STOMACH

was then opened by DR. HERSCHELL. PROFESSOR C. A. EWALD of Berlin gave an elaborate account of the various forms of treatment of gastric diseases which he has used and is still using, but deprecated the over-use of mechanical instruments in diseases of the stomach. DR. R. SAUNDBY advocated, in dyspeptic cases, the advantages of absolute rest in bed. The only sign of ulcer of the stomach which can be relied upon is hematemesis. When this is absent no one is justified in diagnosticating ulcer. Too prolonged feeding by the rectum is a mistake. In this connection Professor Ewald remarked that if the patient who is undergoing rectal feeding loses his pain it points to ulcer. If the pain continues the case is probably a neurosis. The discussion of the treatment was continued in its various phases by numerous speakers. DR. CRAWFORD RENTON of Glasgow discussed the subject from a surgical standpoint.

DR. LOCKHART GILLESPIE then read a short paper on

THE ACTION OF STRONTIUM IODID AND BROMID GIVEN IN COMBINATION IN EXOPHTHALMIC GOITER.

All the patients treated were deaf and dumb, but rapidly recovered under the effect of these salts and experienced no discomfort from large doses.

SECTION ON TROPICAL DISEASES.

The interest in this newly established section of the Association was shown by the large attendance. Representatives were present from France, Italy, America, British Guiana, Central Africa, West Africa, India, China, Malay Peninsula, Hong Kong, Sumatra, and the treaty ports of China and Japan. The President of the Section, DR. PATRICK MANSON of London, delivered an address on the

IMPORTANCE OF A KNOWLEDGE OF TROPICAL DISEASES.

Many of the so-called tropical diseases are absolutely restricted to tropical latitudes and in their native haunts assume phases peculiar to that climate. Many of these countries are not only teeming with an immense native population, but are also being rapidly invaded by the Cau-

casian race. The importance of this subject can scarcely, therefore, be overestimated. The extensions and progress of this branch of medicine during the last twenty years, more especially since Laveran's discovery of the malaria parasite in 1880, have been so great that the study of tropical medicine has become a life's work in itself. Every year the volume of discovery increases, new fields of inquiry are being constantly opened up and the pathological fauna and flora are found to be infinitely more numerous than their congeners of cooler climates. As a special tropical section we have three distinct functions to fulfil. In the first place, we must work for the affiliation and organization of the five or six thousand British practitioners who more or less directly are interested in tropical practice. Five or six thousand is a numerous body; such is its magnitude, however. Secondly, we must insist that those who propose to join our ranks in the future are properly educated in our special branch. We all of us feel acutely the backward state of our educational system in its bearing on tropical medicine. There is not one of us who can not pillory himself with the recollection of lives that perished, entirely owing to the lack, on our part, of the elementary knowledge of tropical medicine. Lastly, we have to discuss the problem of tropical disease. That which has been accomplished has but served once more to show that there is no finality in research; the higher we rise the wider becomes the horizon. Laveran's discovery has illuminated many things that were dark before but it has also opened out new problems and shown dark spots of ignorance hitherto unsuspected. Beyond that which Ross has just told us, we still know absolutely nothing of the malarial parasite as it exists outside the human body. Similarly, we are still in absolute ignorance of the location and of the physical features of the malaria parasite while latent in the human body, or of the exact physical conditions that cause it, after months, or even years, to spring once more into active pathogenic life.

That other great tropical disease, or rather group of diseases, which we call dysentery, is still, as regards many of its forms, their causes, and their treatment, a sealed book. The pathology of liver abscess is still, as it has ever been, *quaestio vexata*. We just begin to know a little about the symptoms, epidemiology, and pathology of beri-beri; we do not know its cause. There is plenty of work for us to do. These are not a tithe of the problems in tropical pathology calling for our consideration. In all pathology there is no such field for fruitful, original research and discovery as tropical medicine.

THE CLASSIFICATION OF TROPICAL FEVERS

was then taken under discussion. The tendency of the thought was to separate malaria from climatic fevers and to differentiate a class apart from either, The subject of ardent fever was keenly taken up and many expressed the belief that the recent theory that would attribute it to infection was not confirmed by experience in India. The fact was brought out that even in latitude 66 degrees north, *viz.:* on the shores of the Gulf of Bothnia in Sweden, attacks of malaria are not unknown. The high death-rate in Africa from black-water fever was presented by Dr. Sanborn, who expressed the opinion that the disease is not an aggravated form of malaria nor due to the influence of quinin. It is most probably a specific disease allied to the hemoglobinuria of cattle, caused by a parasite which has been classed between protozoa and bacteria.

SECTION ON DERMATOLOGY.

FIRST DAY—JULY 27TH.

The President of this Section, DR. W. ALLAN JAMIESON of Edinburgh, in his opening address, dealt with the subject of

REST IN THE TREATMENT OF DISEASES OF THE SKIN.

Various states of unrest calling for the application of this principle were referred to, over-action of the glands and appendages being exemplified in hyperidrosis, seborrhea, and ichthyosis of the nerve-supply in hyperesthesia and pruritus. The inflammatory diseases, eczema, acne, and furunculosis, provide exemplification in another class. Here, the speaker took occasion to refer to the admirable results obtained in erysipelas by the use of ichthyol in strong ointment (20 to 50 per cent.). Spread of the disease is limited and constitutional effects much lessened. In scleroderma pigmentosum, rest and protection from light offer the best results in treatment. [The President later exhibited a child in whom this unmanageable affection had been stopped in its lethal course by the use of ointment containing amber and of thick brown veils, thus preventing access of the sun's rays to the skin.] Even diseases due to parasites alone, tuberculosis, pediculosis, scabies, are often benefited by judicious application of the principle of rest.

After the address the Section adjourned to the Royal Infirmary to attend an exhibit of cases, the best feature of many recent dermatological congresses. Both in numbers and in selection the exhibition proved its worth. Admirable hints as to treatment were dropped in the course of the informal discussion, and contending opinions fairly harmonized. Two cases of scleroderma were shown; one treated by Unna's ointment of bichlorid of mercury (gr. ii-iv–℥ i), the other by the salve and massage, showing striking improvement. One case treated by iodid of potash showed no amelioration whatever. Apropos of a case of leprosy, UNNA of Hamburg remarked that laboratory experience had led him to the use of caustic alkali solutions for the removal of nodules from the face and other exposed parts. The alkali is used in baths as well as in solution or ointment on the skin. Several cases were shown of Duhring's dermatitis herpetiformis in its varieties, the bullous case being assigned by observers to the pemphigus group. Four cases were presented of so-called lichen ruber, two of which UNNA and BOECK of Christiania unhesitatingly classed as parakeratosis variegata, pointing out the ringed character, the rosy, slightly scaling primary lesion distributed on trunk and extensor surfaces chiefly. MALCOLM MORRIS thought several of the cases might be called an early stage of mycosis fungoides. CROCKER supported Unna's opinion.

On the second day interest centered chiefly in the dis-

cussion on lupus erythematosus, a vexed question occupying much attention recently in America. BOECK opened on the side of pathology, saying that the disease in all its forms is an eruptive inflammatory disorder whose special localizations are determined by the vasomotor centers of the skin. It is never a mere local process, although local irritants, heat, cold, etc., play a provocative part, bring the vasomotor disturbance in play. Considering the frequent association of lupus erythematosus and tuberculosis, the latter must play some etiologic part, and is probably the essential cause. The tubercle bacillus has, however, not been found in the tissues, and it is probable that erythematous lupus is due to its toxins, which act first on the vasomotor centers and then locally. The main anatomical changes are: dilatation of the vessels, intoxication of the tissue-cells and, secondary to the latter, inflammation, the whole resulting in atrophy, rarely necrosis.

UNNA, in speaking of treatment, said there exists no rational method, internal remedies having practically no effect. Local applications are best directed by anatomical findings, being directed in general to removal of the horny covering, and to lessening the edema which appears on slight irritation. It is best to begin always with mild, soothing remedies proceeding to destructive only when the uselessness of the former is proved. First use dessicating remedies, powders of zinc, sulphur, resorcin until irritation disappears, then something stronger, such as soft soap, almost a specific, or pyroxalin, an oxidation product of pyrogallol, non-toxic, in paste, or spread as a plaster. Mercury, particularly the ammoniated form, serves admirably, but it should be remembered that greasy bases are not indicated. Pastes should always be used instead. It is rare that recourse should be taken to cauterization in any of its forms. The author has seen absolute cures follow observance of these rules.

MALCOLM MORRIS, on the last day of the meeting, gave an admirable definition of eczema. He describes it as "a disease, the most prominent clinical feature of which is the infinite variety of lesion by which it displays itself, originating in the action of parasites on the skin, the resistance of which has been enfeebled by preexisting disease, structual abnormality, or by disordered innervation, sometimes made more intractable by gout or other constitutional states, but having no direct relation to the general health." As this is the embodiment of the modern conception of this disease, and as it contains every point brought out in the paper, it need not be further amplified, except to say that, while no anatomical basis exists for the assertion, the disease does apparently arise from states of nerve depression.

WALLACE BEATTY of Dublin continuing this debate, said that eczema is anatomically an inflammatory catarrh, clinically attended at some time in its history by exudation. He would exclude from the category all cases in which exudation does not occur. The points of differentiation as from psoriasis, for instance, are localization, itching (?), chronicity, history, and etiology. If it is really and always parasitic, finding of the parasite will in the indefinite future make the diagnosis. UNNA disclaimed any belief in the absolutely parasitic nature of the disease. COLCOTT FOX holds that it is best studied in children, and that it is only a local condition, constitutional disturbances only intensifying it. BARRENDT (Liverpool) is of the opinion that removal of the covering epidermis is the chief cause of eczema; in other words, that it is oftenest a local irritation, but there are cases in which transmissibility and consequent probable parasitism have been proven.

THERAPEUTIC HINTS.

Formula for an Expectorant Pill.—

℞ Terpin hydrat. . . . . gr. xlv
Radicis glycyrrhizæ . . . gr. xv
Ext. glycyrrhizæ . . . gr. xxx.

M. Ft. pil. No. XXX. Sig. Two pills three times a day.

For Infantile Gastro-enteritis.—

℞ Tannigen . . . . gr. xv–3 i
Sacchari lactis . . . 3 i.

M. Div. in chart No. XII. Sig. One powder every three hours in water or food.

For Spasmodic Croup.—

℞ Aluminii . . . . . 3 ss
Vini ipecacuanhæ . . . . 3 iss
Syr. tolutanæ . . . . ℥ ss
Aq. dest. . . . q. s. ad. ℥ iii.

M. Sig. One to two teaspoonfuls every three hours.

For Acute Laryngitis.—

℞ Hydrargyri chlor. mit. . . gr. i
Sodii bicarb. . . . . gr. xxiv
Pulvis aromat. . . . . gr. xii.

M. Ft. chart No. XII. Sig. One powder every hour.

A Diaphoretic Mixture for Bronchitis.—

℞ Morphinæ acetat. . . . gr. i
Potassii acetat. . . . . 3 iii
Liq. ammonii acetat. . . . ℥ iii
Syr. tolutanæ . . . . ℥ i.

M. Sig. Two tablespoonfuls every third hour.

For Pruritus Ani.—

Brocq prescribes frequent enemata of a solution of boric acid in chamomile water, to be followed by the application of a soothing ointment (zinc oxid in vaselin). Lastly, the parts are abundantly powdered, the formula for the powder being as follows:

℞ Camphoræ pulv. . . . gr. xxv
Zinci oxidi, Bismuthi subnitrat. } aa . . 3 vi
Talci . . . . . 3 i.

M. Sig. External use.

Absorbent cotton compresses are used when feasible to keep the powder in contact with the anus. When the irritation has somewhat subsided the parts are painted every other day with a twenty-five-per-cent. solution of silver nitrate. A cocain and belladonna suppository inserted at night may assist the treatment.

ORIGINAL ARTICLES.

ON THE VALUE OF THE AUTOPSIC FINDINGS IN SUBJECTS DEAD FROM SUSPECTED YELLOW FEVER.

BY EUGENE WASDIN, M.D.,
PASSED ASSISTANT-SURGEON, UNITED STATES MARINE HOSPITAL SERVICE.

THE history of yellow fever establishes clearly the fact that it has been, and continues to be, of absorbing interest to all who have come in contact with it, because of the obscurity which has always enshrouded its etiology, the comparative difficulty in diagnosis, and the varying severity of the disease during different epidemics and in different localities. Naturally the question of its diagnosis, upon which depends very frequently the safety of large communities from its ravages, and, *per contra*, the integrity of commercial relations between a suspected place and other reactive centers, is a most important one. For many years the external appearance of the dead body, and that of the internal organs, has been accounted of great value to the diagnostician; and it is of the comparative value of such appearances to one called upon to make a decision under such conditions that this paper treats.

The yellow-fever cadaver has assuredly a most characteristic appearance. All subjects dead from the disease bear a close resemblance to each other; indeed it would not be difficult to make a diagnosis, other facts being favorable thereto, from the cadaver alone. The body is usually quite rigid, this change in the muscles coming on early and persisting. The color is invariably more or less intensely yellow, and is due to a mixed hepatogenous and hematogenous jaundice. The entire skin is tinted, the scalp usually presenting a startling contrast to the parted hair, and the whites of the eyes are yellow, the change taking place in the conjunctivæ early in the disease, the scleræ becoming tinted later. This yellow tint is always contrasted with the deep purple discolorations from hypostasis which quickly appear in the skin of the dependent portions of the body after death, and which frequently appear before. It is at the edges of these hypostatic areas that the mixture of biliary and blood jaundice is particularly noticed as a muddy, thick, grayish-yellow tone. Hypostasis is common to all cadavers, but particularly is it prominent in this disease. It is not confined to the lower portions of the body, as the buttocks, loins, and shoulders, but invades the neck, chest, ears, and face; the genitals, as a rule, and the finger- and toe-nails, are of a deep purple color. This discoloration occurs quickly, and is prominent within an hour after death. The pupils are usually dilated, the tongue foul, and the gums bloody; the anterior nares are caked with blood. This is a picture of a typical yellow-fever cadaver, and the appearances may be accentuated or softened, but the characteristic ensemble will be present in all.

My experience in autopsies on subjects dead from malarial fever in the South, has shown me that there are externally many points of resemblance in them to the yellow-fever cadaver, and at times I feel assured the decision between them would be very difficult or impossible. Dependence must then be placed upon the conditions found in the internal organs. Section shows deep yellow tinting and dryness of the superficial tissues and the peritoneum, a glazed appearance of the intestines, which are dry and sticky to the touch, and a deep-tinted peritoneal fluid. The organs are of a yellow tint, ranging from light to deep saffron. The omentum is deeply congested, the dilated, purple veins contrasting with the general tint. The spleen is usually of normal size and appearance; any deviation suggests preceding or complicating disease. The kidneys are always congested and swollen; the stellate veins of the capsule are prominent; the capsule itself is not influenced by the disease; frequently there are extravasations upon the cortical surface. Incision of the organs shows congestion of the renal veins, yet the general appearance is pale. The cortex is swollen, its markings usually obscured, and at the bases of the pyramids of Malpighi there are seen pale yellow fatty areas. These are very generally seen, and in cases of long duration a general fatty appearance is present. I would attract especial attention to these fatty areas about the base of the pyramids within the cortex, for they can be seen when the kidney otherwise appears free from fatty change. The adrenals are normal. The urinary bladder is usually empty, from anuria; its mucosa may present extravasations. In one case only have I known bloody urine from such extravasation. The mesentery is always typically congested, yet I have but rarely seen extravasation in its layers; the congestion is more marked in the reflection upon the duodenum.

The liver, long considered the pathognomonic organ, may or may not be normal in size, but any deviation from the normal I consider dependent upon some other cause, for if the histology is considered it will be seen that upon the increased amount of blood in the vessels depends any increase, while the termination of the disease must anticipate noticeable decrease in its size, from absorption of the fatty detritus. I have usually found the organ normal in size. The gall-bladder is generally empty, owing to intra-abdominal pressure from vomiting and decreased secretion, but may contain a normal amount of bile. The color of the organ varies from a light buff, or "box-wood," to a dark brown, this seeming to depend upon the amount of congestion, the left lobe and upper portions being, as a rule, lighter in color than the right and more dependent portions, the posterior surface being a dark blue from stasis. At times this fatty appearance is diffuse, and again there may be only plaques of yellow upon the surface, or throughout the organ. A frequent appearance is that of the so-called "nutmeg" liver, the yellow points contrasting with the red lines about them. Upon section, the liver, if not the subject of preceding disease, presents a normally firm resistance, is of firm consistence, at times friable and dry, of a pale yellow color, and imparts to the blade a greasy stain. The portal vessels are full of dark fluid blood, which changes to carmine on exposure to the air. The venous radicles are distended, the adjacent parenchyma showing fatty change, and this contrast results in the "nutmeg" appearance. The smaller bile-ducts are empty. The capsule is normal. The vessels of the stomach walls are congested, also those of the omental reflections. The stomach may contain more or less blood-stained fluid, which if exposed to the acid secretion for some time may have the "coffee-grounds" appearance. Frequently the content is a thick, glairy, grayish mucus, which clings to the mucosa. The mucosa itself is invariably thickened, swollen, and presents numerous patches of extravasation and shallow erosions. While the entire membrane may be affected, the changes are more marked on the anterior surface and near the pylorus, the membrane here presenting a deep port-wine stain from diffuse extravasation and often evidence of free hemorrhage. If many hours have elapsed between demise and autopsy the membrane will be found much softened and with many erosions from post-mortem change. The vessels of the duodenum are engorged; the mucosa is swollen, eroded, and hemorrhagic; in some instances it contains black, grumous blood, from which the stomach is free. The mucosa of the entire canal may present evidences of ante-mortem congestion in the form of minute extravasations. In the female there may be extravasations in the ovaries or the mucosa of the tubes and uterus. The vessels are prominent on the surface of the diaphragm.

Within the thorax the general yellow tint prevails, there being nothing notable about the lungs save congestion; the pleuræ frequently present ecchymoses. The pericardium, both visceral and parietal, also is frequently ecchymotic. The heart is usually in diastole, or the left ventricle may be rigidly contracted from change in the muscle, the right being always dilated with dark fluid blood. There is always present a very notable congestion of the vaso vasorum of the great vessels at the base of the heart, these minute vessels forming a delicate tracery over their serosa and upon the walls of the auricles, which at times present minute ecchymoses. I deem this a very constant and characteristic appearance. The heart muscle does not show fatty changes very often to the unaided eye. The fluids of the pericardium and pleuræ are yellow. The changes in the brain and its membrane are those of intense congestion, the fluid of the ventricles being yellow, and there may be extravasations.

Such are the findings in a typical yellow-fever cadaver. It is sometimes said that a yellow-fever autopsy is a bloodless one, but this expression must have arisen because of the limited scope of many hastily made sections, which consist in an exposure of the liver and its incision; the extraction of a kidney, and the exploration of the stomach *in situ*. In reality, the full influence of the toxin is felt upon the vasomotor system, and results in an incomparable congestion of the vessels of the abdomen, and when complete the section presents an appearance quite the reverse. A study of the histopathology of the organs must be limited to the examination of fresh sections from the liver and kidneys, for in these the fatty changes are best seen. The liver cells are more granular, stain more faintly, and contain numerous fat-droplets; those of the kidneys lining the tubules, especially of the cortex, are also filled with drops of fat. These gross changes are readily detected, and if facilities are at hand they should be sought for. But the importance of an immediate diagnosis will have long passed before the finer histologic changes may be observed.

I have said that the above appearances are constant in the cadaver of yellow fever. The question then arises as to their diagnostic value. Is it possible to arrive at definite conclusions from an isolated case presenting all of these signs? Would we be justified in such cases either in withholding quarantine protection from a community, or in initiating quarantine to the possible detriment of commerce?

The last phase of the question is a most important one, and at times exercises as much influence as the first. From recent observation I feel safe in asserting that it is not possible to diagnose this disease from the appearances and the gross microscopic findings alone. I do not undervalue their importance when taken in due consideration with the history of the case, the clinical charts, and the history of albuminuria, in assisting to form an opinion, but in the absence of these accompanying facts they are not sufficient to name the disease, although a diagnosis may be safely ventured in the absence of any other known cause of infection.

Just here I will venture tentatively upon the question of etiology as having a direct bearing upon what has been said. All observers in this field have recorded the presence of the bacillus coli communis in its many forms in the blood of patients living, and more freely in the blood and tissues of those dead from yellow fever. Sternberg, in 1889, discovered, among other forms in the tissues of such patients, a bacillus of such peculiar physiologic and vegetative characteristics that he assumed for it a distinctive position among these organisms, and from its influence upon animals, a possible etiologic value in this disease. This was bacillus X. In 1897, Sanarelli, of the University of Montevideo, published his discovery of a bacillus which, he claims, causes the disease, and which he named the bacillus icteroides. These organisms present many similar features of growth and chemic reaction, yet there are sufficient distinguishing characteristics to ensure them separate places in the group of colon organisms; for during my observation upon these, and other organisms from yellow-fever cases, it became evident that the former belonged to this group, and it appears probable that the bacillus of Sanarelli was alone to be classed among them. On September 28, 1897, it was my privilege to observe a case of yellow fever at the isolation division of the Marine Hospital Service detention camp at Fontainebleau, Miss., in the person of one Goodrich, and from cultures from his blood on the fourth day of the disease (which was well marked) to isolate a bacillus, which corresponded to that of Sanarelli, from a contaminating colon bacillus. This was designated bacillus "Goodrich," and was esteemed the first organism isolated after Sanarelli in this country. Later, in the City of Havana, and in concert with my colleague, Passed Assistant-Surgeon H. D. Geddings, United States Marine Hospital Service, this bacillus was isolated from a number of cultures taken in the Isolation Hospital in New Orleans during the epidemic of last year. Besides the organisms isolated by us from these native sources, it was our privilege to study a limited number of cases of yellow fever in the military hospitals of Havana, and in sixty per cent. of these we isolated the same bacillus. In all of these instances this organism maintained its distinctive characteristics from the bacillus X.

Experimental inoculations with these organisms were usually fatal to animals, which exhibited more or less pronounced rapid or prolonged symptoms of intoxication, but necropsy always gave similar appearances in the different organs. As an example I give the notes from an autopsy:

Pig No. 2, white female, weight 525 grams, was injected intraperitoneally with 1 c.c. of a twenty-four-hour bouillon culture of bacillus "Goodrich" at 3 P.M. on February 9, 1898. On the morning of the 10th the animal exhibits evidence of distress, does not eat, remains crouched in cage; abdomen tender. Temperature, 37.3° C. (99.2° F.); respirations, 80. At 3 P.M. the animal is quite ill, and has lost 42 grams in weight. At 9 A.M. on the 11th it died. Necropsy immediate. Body still warm. Heart first exposed; in diastole and full of dark fluid blood; the vaso vasorum distended over the great vessels at the base; pericardium and fluid slightly tinted. The liver is congested with numerous plaques of a yellowish-white fatty appearance; when incised this fatty appearance is general. The spleen is slightly increased in size and congested. The kidneys much congested and swollen. The urinary bladder contains 6 c.c. of urine which, by the cold nitric-acid test, gives a dense ring of albumin, and which is also shown with heat and nitric acid. Peritoneum not inflamed; some injection at the point of puncture to left of median line; in the left iliac fossa there is a small quantity of cloudy fluid localized. Mesentery normal save an intense engorgement of its vessels, especially in its duodenal reflection. In the stomach the mucosa is congested, thickened, and softened, especially about the pylorus; that of the duodenum much congested with numerous small extravasations, but no free hemorrhage. Cultures from blood of organs, and from the fluid from the fossa, give, after twenty-four hours, colonies only from the latter. This is a pure culture of the inoculating organism. After forty-eight hours tubes from the left pleural fluid also exhibit colonies of this organism in pure culture, the spleen also giving a colony free from contamination. Cover preparations show only a small characteristic rod in pure culture from the fluid in the iliac fossa.

In this case there was no free blood in the stomach or bowel, but in the very next of my series there is this note: "Mucosa (stomach) injected and near the pylorus there are ecchymoses and at one point at least there is free hemorrhage, which has stained the food-mass a dark or black color. This looks like 'coffee-grounds.'" This experience has been that of many other observers. These organisms elaborate a toxin which exerts a characteristic and

powerful influence upon the vasomotor system, as evidenced in the intense engorgement of the vessels, the gaseous, toneless pulse, and the full diastolic heart, prior to and post-mortem; also, in that rapid metamorphosis of the albuminoids of the highly organized cells of the liver and kidneys. The intention is not to contrast these organisms, but to accentuate the fact that there is no constant sign at these autopsies by which we can name the particular one which has produced the disease.

Here I will revert to the subject proper, the value of these post-mortem appearances in the human body. And again I must refer to notes kindly furnished me by Dr. B. E. Baker, of the Army General Hospital at Key West, Florida, in order to illustrate their value. The U. S. S. "Yankee," cruising on the southern coast of Cuba during June, 1898, entered Key West harbor. She sent to the hospital a seaman ill for one week with appendicitis. Her officers later stated that a few Cubans had been entertained on board during the cruise, and that several boat crews had been sent on board of captured vessels for the purpose of destroying them, but that no baggage or effects had been allowed on the vessel excepting four dogs and a few machetes. On the third day after entering the hospital, and second after operation for appendical abscess, the patient developed high fever, became delirious and died on the fourth day, the entire illness having lasted about ten days. Prior to death the acute exacerbation (the temperature having fallen to normal after the operation) and the mental symptoms attracted attention. The skin was noticed to be jaundiced and suffused, as were the eyes. The urine contained no albumin at this time, but was found to contain it after death. At autopsy the general appearance of the body impressed the operator, Dr. Baker, with the probability of its being the subject of yellow fever, and I was called in consultation. After a careful examination of the body and organs I concurred in the diagnosis of yellow fever.

Necropsy made five hours after death. White male adult, poorly nourished; rigor marked; conjunctivæ slightly jaundiced; pupils normal; post-mortem lividity on back and neck and dependent portions of the body, on scrotum and prepuce; the face, neck, and anterior portions of trunk a bronze yellow color, not so marked on the legs. On section, there is about 12 c.c. of clear bile-stained fluid in the pericardial sac; the membrane contains a few ecchymotic spots in its reflection over the diaphragm; the visceral reflection also is ecchymotic, and presents extravasations of blood well marked at the base of ventricles; the vasa vasorum distended; the heart normal in size; the left ventricle contains small amount of soft blood-clot; the right auricle and ventricle distended with dark fluid blood; valves competent, muscle is pale and yellowish; aorta tinted, some atheroma about valves. The pleuræ shows old adhesions; the lungs are normal. The abdominal cavity is dry; the intestines sticky; the mesentery and the omentum show ecchymotic patches; the glands are enlarged. The spleen is normal in size and color. The kidneys are slightly increased in size; congested; the stellate veins of the capsule well marked; the inner edges of the cortex, near the bases of the Malpighian pyramids, show a yellowish tinge; suprarenal bodies normal. The liver is normal in size, of typical nutmeg appearance, with lemon-yellow areas and spots scattered over the surface; the gall-bladder contains 45 c.c. of thick greenish black bile. On section the liver presents a typical nutmeg appearance, and much congestion. The stomach is somewhat dilated and contains 250 c.c. of brownish black fluid with brown granules; the mucosa is congested throughout, but especially on the posterior wall near the cardiac extremity. (When washed there were great plaques of deep wine-colored extravasation and numerous erosions.) The mucosa of the duodenum is ecchymotic, and there is free hemorrhage in the form of "black vomit." The last inch of the ileum is bound down by adhesions, as are the caput coli and the cecum. On freeing the gut a small abscess cavity is seen between it and the abdominal wall, in which is the vermiform appendix, with a slough in its distal portion, the upper two-thirds being normal. (This cavity was drained through an incision in the abdominal wall.)

In this case there was no doubt in my mind that death had been caused by infection with one of the organisms of the group already named, but with which one? Here there was an acute appendicitis, with localized abscess, and perfect drainage. Was it clear that death had taken place from a general infection from the colon group? Not at all, for this patient had possibly or probably been exposed to the infection of yellow fever through the presence on board his ship of persons who may have conveyed infection in their clothing. The time elapsed since such possible exposure was about the incubation period of the disease. If we assume that the fever developed in the hospital it must have been contracted on the ship, since there has been no yellow fever in Key West during the present season. In this remarkable case, remarkable because of the element in it of serious possibility, amounting to probability of exposure to the infection of yellow fever, contrasted with the fact of local if not a general infection with

the bacillus coli communis, I concurred in the diagnosis of death from yellow fever honestly, for this was a yellow-fever cadaver as we know them from external appearance and anatomical facts. However, I am now convinced that it was simply an intoxication from auto-infection with some member of the colon group of organisms. For, notwithstanding the fact that the crew of the "Yankee" was composed of young Northern men, the New York Naval Reserves, and that the surgeons, nurses, attendants, and neighboring patients were reagents, there has been no sequel to the case, nor is it reasonable to assume that this seaman, ill in his cot from appendicitis, should have been the only one of all the reagents on this ship to have contracted the possible infection.

The city of Key West was the base of naval operations against Spain. Its poor sanitary condition, the presence of a large number of non-immune residents, and the necessity of keeping the base open, all seemed to me to demand the diagnosis which we made, for under the circumstances the only harm possible would be the restraint placed upon the inmates of the hospital for the prescribed time and extra vigilance upon the part of the medical officers on board the ship. Only a few minutes after the post-mortem one of the medical officers, a reagent, asked me, "How much danger of infection have I risked from my presence at the operation upon this subject, and my having visited it several times since?" I replied: "None, provided this man has not come into contact with the infecting agent of yellow fever." Moreover, I felt willing to assume the responsibility, provided also all blame in continuing the routine of the hospital without other restraint than strict vigilance until some sequel demanded its isolation. However, was the autopsy in this case of material assistance of itself? In the absence of any history of possible infection could any one, familiar with the appearances in the organs of animals killed with the organisms mentioned, and comparing these with those found in yellow-fever organs in man, have unhesitatingly decided in this case? Yellow fever, clinically studied, has impressed many observers, since I have heard it frequently expressed among the profession of Southern cities that it is a disease in which probably two etiologic factors are present, the primary or external agency, giving rise to the initial symptoms of the disease, and a secondary or internal agent of auto-infection. Is it not possible from what has been shown that the auto-infection may be productive of the autopsic appearances? This view of the disease is reasonable, but not yet proved, nor will it be until the indubitable cause of yellow fever is discovered, that is, an agent which not only can give rise to the appearance of yellow fever, especially post-mortem, but can, as in the case of the bacillus of diphtheria, give rise to an acute dissemination of the disease among those who are reagents. This has not been demonstrated either in the case of the bacillus X. or of bacillus icteroides. We should not hastily decide upon the etiologic value of an organism, so closely allied to the colon group as are the two named, from the influence exercised upon the sick by the exhibition of its antiserum, but depend rather upon its power to reproduce the disease, "catching" from person to person, and of the antiserum to prevent such infections. Finally, I would suggest that typical autopsic findings should always be regarded with suspicion, and demand immediate investigation of their cause. Should there be, or not, any local center of auto-infection, there should be an investigation of the immediately preceding history of the patient, and should there prove to be evidence of exposure to infection of yellow fever, and should the clinical charts and history present the evidences of the disease which we have learned to recognize, then and only then can the information gained post-mortem be of decisive value to the diagnostician.

CATGUT SUTURES AND LIGATURES.[1]

BY HOWARD A. KELLY, M.D.,
OF BALTIMORE;
PROFESSOR OF GYNECOLOGY IN JOHNS HOPKINS UNIVERSITY.

SHALL we continue or shall we discontinue the use of catgut in gynecological surgery? is a question of great practical import and one which, in view of the tens of thousands of clinical experiments made by the members of this Society in the aggregate, we ought to be able to answer definitely to-day.

The importance of any given suture is enhanced or depreciated by the relative qualities of other suture materials, their durability and their liability to lodge sepsis. The alternatives to the catgut suture are silk, silver wire, and silkworm gut. A further matter for investigation is the relative value of these materials for sutures and for ligatures. In general, if I had to abandon all sorts of sutures and ligatures but one, I would unhesitatingly prefer to keep catgut as the one which unites in itself the most advantages with the fewest drawbacks. Having, however, a choice among the four materials mentioned, I am accustomed to discriminate with regard to certain of their peculiarities and to employ one or the other, or all of them in a given case. Catgut should not be used exclusively for these two

[1] Read in the discussion on "Should Non-absorbable Ligatures Be Discarded in Gynecological Surgery?" at the Twenty-third Annual Meeting of the American Gynecological Society, held at Boston, May 24, 25, and 26, 1898.

reasons: it does not bear tension well, and in surface work it is liable to infection. The great danger of catgut is the absence of scientific bacteriologic control of its preparation from the raw state and its liability in occasional instances to harbor infectious organisms. This, which was the burning question of ten years ago, has now been definitely set at rest by the cumol sterilization of catgut, by which the hydrocarbon at a temperature of 155° to 160° C. renders the gut sterile beyond a peradventure. By this means the whole question as to the propriety of using catgut has been placed upon an entirely new basis, and the query is no longer as to the possible risks, but as to the intrinsic properties of the material as a suture and as a ligature. With a suitable apparatus there is no danger from the explosion of the cumol during the process.

I do not feel able to express an opinion as to the possibility of sterilizing catgut by prolonged boiling in alcohol, even under pressure, or as to the bactericidal power of the formaldehyd solution. I look askance at the dry-heat methods of sterilization so extensively used throughout the West.

Before the advent of the cumol method of Menge, and the cumol dry method as suggested by Clark, I lost three cases where I could trace the deaths from septic peritonitis to no other cause than the catgut. Since using this method I have never seen a single instance of infection where there was the slightest reason to suspect the gut, although I have used, I believe, on an average, about fifty strands a day for more than two years past.

My experience with catgut is limited to the lighter strands; stout, heavy catgut I have never used. I consider catgut the ideal ligature for vessels of small size, and I have used it without stint in controlling hemorrhage, except for large vascular trunks, such as the internal iliac and uterine arteries, where I use light silk. I had a case of death about two years ago from the absorption of the catgut ligature applied to the right uterine artery after a supravaginal amputation of the uterus; the bleeding occurred about the eighth day and was fatal before we could check it. Since using silk only in this limited way, and using catgut extensively in the abdomen, I have never had to fish out my ligatures after operations.

In the plastic work in the vagina I take the tension off the areas to be held together by a single silkworm-gut suture on the cervix holding the lips together, and in the vagina loosely approximating broad denuded areas; the catgut then comes in to do the work of accurate approximation where there is no tension.

In the abdomen I sometimes use a single fine silk suture to draw the lips of the cervix together in the middle, and fine silk ligatures on the large vascular trunks, all the rest of the ligating and suturing being done with catgut.

In the abdominal incision I have long used catgut throughout, in three or in four tiers, for incisions two inches long or under; in longer incisions, in approximating the fasciæ and recti, I divide the wound up as suggested by Dr. W. Russell, by silver-wire mattrass sutures, placed about an inch and a half apart, and then use catgut in between. The wire takes the tension and the catgut secures accurate union between.

In genito-urinary work, catgut is safe in the cortex of the kidney, and it has proved safe in uninfected cases wherever I have used it, even where it has shown on the mucous surface. It is absolutely safe in the muscular tissue outside the mucosa. It is not safe when there is any decomposition of the urine.

I have used catgut with the loops of the sutures appearing on the mucous surface of the bladder, and after the absorption of the buried portion of the suture, the loop was discharged by the urethra.

The best way to use catgut in the genito-urinary apparatus is to bury the entire suture in the tissues lying outside of the mucosa; treated in this way they act like buried catgut sutures at any other point. If there is any tension to be overcome I then prefer using fine silk in my urinary work, if the silk is buried so as not to appear on the mucous surface; it never does harm and does not have to be removed. I think with silk of this fine sort and with catgut we can best close all wounds of the upper urinary tract and involving the bladder above its base. More powerful sutures are often necessary to overcome the tension produced by bringing together the tissues at the base of the bladder, as for example in vesico-vaginal fistula. Even here, however, I think we will do better if we free the bladder from the vagina on all sides so that it comes loosely together, and then close it with the fine silk and catgut sutures.

Permanent sutures of any sort whatever attract the urine salts, and form calculi if they are exposed to the contact with the urine. In this way calculi have been removed containing, as a nucleus, silk, silver-wire, and silkworm gut.

The Accommodations at Montauk.—The hospital accommodations at Montauk are still deplorably lacking in number and in convenience. The general hospital, which was built to accommodate 500 patients, already contains 1100, so that the sick are badly crowded. The result is that the sick men in the various commands are perforce thrown back upon the regimental hospitals, which are nothing but ordinary privates' tents—some of them occupied by the well as well as the sick.

HYPNOTISM IN PREGNANCY AND LABOR.[1]

BY LOUIS LICHTSCHEIN, M.D.,
OF NEW YORK;
ASSOCIATE PROFESSOR OF NERVOUS DISEASES IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE; NEUROLOGIST TO THE WEST SIDE GERMAN DISPENSARY.

THIS subject is one of the very greatest importance to every general practitioner in whose sphere the phenomena accompanying pregnancy rightly belong. I shall leave out of consideration psychic influences that can be brought to bear upon the fetus, for though the possibility of such influences is supported by facts, they are regarded as mere coincidences. I shall not touch upon the mode of action of suggestive therapeutics in general; that I have detailed in a paper, entitled "Hypnotism as a Therapeutic Agent," which was read before this Association, and published in the *New York Medical Journal* of May 30, 1896. For purposes of convenience I shall divide my subject into three parts, describing my experience with the hypnotic treatment first in the pathologic conditions of pregnancy, then in normal labor, and, finally, in the puerperal state.

As regards the first subdivision, there are, I think, only three abnormal conditions in pregnancy in which suggestive therapeutics may be of use. These are: (1) hyperemesis gravidarum; (2) anorexia, with disgust for certain articles of food; (3) abnormal craving for particular foods, and especially for unpalatable substances which are usually not regarded as food. Simple vomiting occurring once or twice a day is an almost constant physiologic condition of conception and pregnancy. It is usually not very troublesome, and as pregnancy progresses it generally ceases spontaneously at the end of about the third or fourth month; in most cases, therefore, it is not a symptom that requires any interference. The case is different, however, when the vomiting lasts beyond the usual time, or when it is so frequent and violent that the patient's nutrition is interfered with, thereby impeding the process of digestion and threatening the well-being of the mother and lowering the vitality of the child.

The worst types of this condition, vomitus gravidarum perniciosus, imperatively calls for interference, for the persistent rejection of food is a menace to life itself. Every practitioner is acquainted with this condition of slow starvation, aggravated by the continuous gagging and vomiting soon after the ingestion of foods or liquids. The etiology of pernicious vomiting is still an unsolved question. Is it a reflex irritation of the stomach caused by an irritation of the nerves of the uterus, or is it an irritation of the center of vomiting dependent upon an alteration of the intracranial pressure, or is it a disturbance of nutrition of the central nervous system, as some authors assert? We do not know. Horwitz claims that it is due to a parenchymatous inflammation of the uterus, and especially of the fundus. Graily Hewitt thinks the cause of the reflex irritation of the nerves is the pressure of the gravid uterus upon the nerve terminals. Bretonneau finds its cause in the inverse ratio of dilatation of the uterus to the growth of the ovum. Experience has taught us that either the intra-uterine death of the fetus or the spontaneous or artificial expulsion of the child, or sometimes dilatation or cauterization of the cervix uteri, will put a stop to the vomiting. Drugs and dietetic measures do not seem to have much effect upon this condition, but it has sometimes been observed that mere change of location or environment, such as is effected by the temporary return of the patient to a former home or to the house of her parents, will also relieve the vomiting. Being thus amenable, in some cases at least, to psychic influences, it has been thought worth while to try suggestive therapeutics, the influence of which is more powerful in this form of abnormal pregnancy, and more especially in cases in which the environment could not be changed. This has been tried in such cases very often both in Europe and in this country with good results. Permit me to cite a few cases of my own to show its action.

CASE I.—Mrs. I. K., thirty-two years old, born in Hungary, had three children. She came to me in the second month of her fourth pregnancy. I had previously relieved her of a facial neuralgia by suggestion, and she now asked me to do something for her vomiting. She had suffered from the same trouble during her former pregnancies. In these vomiting had occurred many times daily during the whole nine months of gestation, and though she had suffered continually from hunger and thirst, she had never been able to retain more food than was just sufficient to keep her alive. I hypnotized her. After the first séance the vomiting ceased entirely. To ensure the permanency of this result and counteract the feeling of disgust for certain articles of food, such as meat, etc., that she sometimes experienced, I repeated the suggestions several times. One suggestion was usually enough to cause her to like food which was previously unbearable to her. The entire subsequent course of her pregnancy was free from vomiting, and her general condition remained excellent.

CASE II.—Mrs. B., twenty-one years old, born in New York of Irish parentage. In the fall of 1896, toward the end of the seventh month of her pregnancy, she began to suffer from uncontrollable vomiting. During the previous months she had vomited regularly once or twice daily, but the emesis

[1] Read at a meeting of the Medical Association of the County of New York.

was not violent, and she was able to retain enough food to feel fairly well. She had taken cold while at the seaside, was coughing, and the vomiting had then become so persistent that she could not retain any foods or liquids at all. For four weeks two physicians had tried to stop the vomiting with various drugs, but it became worse, until at last even the smallest quantity of liquid was rejected. She was emaciated almost to a shadow. She was literally starving, and during the last few days the rejected food was mixed with blood.

The husband, whose mother and sister I had had occasion to treat hypnotically, called me in consultation with the attending physicians. They proposed to dilate the cervix uteri, that, in their opinion, being the *ultimum refugium*. I advised a trial of hypnotic suggestion, but they did not agree with me as to its advisability. I then asked a trial of twenty-four hours, remarking that if at the end of that time suggestion did not succeed there would be time enough to resort to dilating the os, which procedure might or might not be followed by abortion. My advice was finally accepted, and I hypnotized her. She went only into a superficial sleep, yet on awakening she could eat and retain a small amount of food. I hypnotized her once daily for three days. Of course, the usual dietetic measures were not neglected. During these three days she did not vomit. She ate fairly well, and began to feel stronger and be more cheerful. On the evening of the third day of my treatment a female relative came to see her, and expostulated with her concerning the treatment, saying that the doctrines of the Catholic Church were opposed to hypnotism and mesmerism, and that she would be excluded from confession if she were to continue. This threat naturally excited her greatly, and so preyed upon her mind that she began to vomit again. The husband went to her spiritual adviser, and he confirmed what her relative had said. I received notice to cease my treatment.

On the fifth day following I was called in again. The priest had been there that morning, had seen the continuous vomiting, the blood-shot eyes, the blood oozing from nose and mouth, and thereupon obtained a dispensation from the bishop of the diocese, so that the treatment could be recommenced. Hypnotic suggestion again stopped the vomiting immediately. For two days she enjoyed this tranquillity, when suddenly and spontaneously labor set in, and she was delivered of her child in a few hours. The suggestive treatment, now unnecessary, was stopped. During the puerperium it turned out that the catarrhal symptoms which she had manifested during pregnancy were but the forerunners of acute tuberculosis, which caused her death four weeks later. During this last sickness Dr. A. Jacoby was called in consultation, and it was his opinion that the vomiting was due to tuberculosis. Whatever its cause, the fact remains that the vomiting was cut short by suggestion, and, perhaps, if earlier resorted to for relief of the symptom, it would have prevented the tuberculosis making such headway.

CASE III.—Mrs. W., twenty years old, had already been relieved of a long-standing illness by hypnotic suggestion when she became pregnant for the first time. The first months of pregnancy passed off well; there was only occasional vomiting. In the fifth month, however, she began to reject all food. After suffering four days she sent for me. A single suggestion in deep hypnosis sufficed to change her condition. The vomiting ceased entirely.

The other two abnormalities of pregnancy, loss of appetite, and the craving for articles not to be regarded as food, can be readily relieved by suggestion, even though the hypnotic condition into which the patient is brought is not deep. I could support this assertion by illustrative cases, but shall abstain from doing so in order not to unduly prolong this paper. In labor, also, hypnotism can be used to advantage. I have not had the opportunity to use it in complicated cases, such as those requiring version or the use of the forceps. I do not doubt, however, that in patients belonging to the fifth class, to be mentioned below, suggestion may be successfully employed when operating, but in cases in which hypnotism may be used successfully, it has a decided advantage over chloroform, the disadvantages of which I need not here recount to you.

In studying the effects of suggestive therapeutics in normal labor we may divide the patients into five classes: The first class comprises the patients who cannot be hypnotized; the second class includes those patients who only sleep superficially, awakening at the very first pain, but with whom the suggestion has a decided post-hypnotic effect. To the third class belong the patients who sleep deeply, but in whom the sensation of pain overcomes the suggestion, so that when it becomes violent they wake up. There is amnesia for everything that happens intrahypnotically, as well as the post-hypnotic effect of the pain being much less than the circumstances would appear to warrant. In the fourth class we may place those who sleep very deeply. These do not wake up; the whole labor is conducted intrahypnotically. After awaking there is perfect amnesia. The fifth class comprises those patients with whom the post-hypnotic effect of suggestion is all-powerful, so that though labor is going on in a waking condition pain is absolutely not felt.

My experience is rather limited here. I have tried hypnotism in forty-six cases only. Nine patients could not be hypnotized at all, 11 slept superficially with post-hypnotic effect, 15 slept deep with intrahypnotic and post-hypnotic effect, 10 had a very deep sleep with perfect amnesia upon awakening, and 1 was awake but felt no pain at all. I may add that the twenty patients belonging to the first and second

class were mostly women of nervous temperament and such who were biased against hypnotic measures. Almost all of them expressed a fear lest something would befall them during sleep. I shall cite an illustrative case in each of the last four classes.

CASE IV.—Mrs. B. L., thirty years old, German, of nervous temperament, third pregnancy. Came to me at the middle of the eighth month of her pregnancy. She had heard of hypnotism, and said she would like to make use of it, as her two former confinements had caused her a great deal of suffering. I hypnotized her at once. She went into the second degree of Bernheim's classification, and I suggested to her that in her third confinement she would have no pain. Before her confinement I hypnotized her three times more. The sleep was never deeper than the second degree, and each time I renewed the suggestion of a painless confinement. March 14, 1895, at 8 P.M., she began to have labor pains. I hypnotized her once more, again only to the second degree, and suggested that the bearing down would increase every time, but that she would feel no pain. Though the contractions of the uterus came on with fair regularity, the patient experienced little or no pain, but woke up with the first stronger contraction. At 8.45 P.M. the os was dilated to the size of a silver dollar; at 9.30 the dilatation was of twice that size. From this time on the contractions were more frequent, coming on every three or four minutes. Each time she had some pain, but it was so moderate that she complained of labor progressing so slowly. Nevertheless, at 10.30 the os was entirely dilated and the membranes ruptured. Now came a lull for about ten minutes, after which the contractions came on again with increasing strength, and were accompanied by considerable pain until at a few minutes before 11 P.M., the child was born. She said that in comparison with her former confinements she did not suffer at all.

CASE V.—Mrs. Bertha H., twenty-eight years old, German, married ten years, third pregnancy, five years after the last; robust; had never been sick. Up to the time of labor I hypnotized her three times. She went into a deep sleep with amnesia upon awakening on suggestion only. She was, therefore, in the seventh degree of Bernheim's classification. June 9, 1895, 6 A.M., labor set in. I arrived an hour later and hypnotized her. The pain that had previously accompanied every contraction disappeared on suggestion. The contractions came on rather slowly, so that at 10 A.M. the os was dilated only to the size of a silver dollar; suggestion seemed to have but little influence on the intensity of the contractions, but she felt no pain. I then left her for about two hours and a half, returning at 12.30 P.M. The os was dilated to about twice its previous size, but the contractions had ceased about half an hour before. She seemed to sleep only superficially. I awoke her and hypnotized her again. She then slept more deeply. I suggested that the uterus would contract again more strongly in three minutes, and that at the time of bearing-down she would help along with the abdominal muscles. The suggestion was now successful. From this time on the contractions became regular, frequent, and strong, but still there was no pain. At 2 P.M. the os was entirely dilated and the membranes ruptured. A few minutes later, at the height of a contraction, she seemed to have great pain and woke up. I could not put her to sleep again. The bearing-down, now growing still stronger, was always accompanied by pain, but, curiously enough, not as great as that which awakened her. This could only be accounted for as being the post-hypnotic effect of the former suggestions. The expulsion of the child followed fifteen minutes later. She could not remember anything that happened up to the time of her awakening.

CASE VI.—Mrs. I. K., thirty-two years old, born in Hungary, fourth pregnancy. I had hypnotized her repeatedly before for another affection. She always went into the deepest sleep possible. I was called October 21, 1895, at 12 M. She had had some labor pains since morning. At 11 A.M. they had grown stronger, and she sent for me, but a short time before I arrived the pains ceased entirely. On my arrival I ascertained that the os had dilated to about an inch in diameter. I then hypnotized her. On suggestion, the contractions of the uterus began again and continued regularly as commanded. Drs. Morvay-Rottenberg, Sigismund Cohn, and Mandel, whom I had invited, were alternately present. This patient, although in deep sleep, seemed to have some pain with each contraction. She acted as if she suffered, but when asked if she did, said that she felt the bearing-down and had then an uncomfortable feeling, but no pain. She conversed cheerfully upon different topics, there being only a slight interruption in her speech, a twitch of the facial muscles, or sometimes a groan to tell me that the uterus was contracting and that she was helping it along. On inquiry she always denied having pain. At about 4 P.M. she complained of some pain in the right side, but gentle friction of the site made it disappear. About 4.50 P.M. the membranes ruptured, and a few minutes later the head came down to the perineum. The contractions now became so strong and the pressure so great that I had to suggest that they become weaker in order to preserve the perineum. The bearing-down immediately became less strong, though still sufficient to dilate the vulva. A little after 5 P.M. the child was born, and five minutes later the placenta came away spontaneously. After the patient had been washed and made comfortable I awoke her. She was astonished to find herself delivered, and although she had been told before awakening that she had given birth to a boy, she had to ascertain the sex of the child anew. There was perfect amnesia for everything that transpired since I had put her to sleep.

CASE VII.—Mrs. I. L., thirty-four years old, fifth pregnancy. I had delivered her hypnotically once before. Sleep was the deepest possible. I hypnotized her once in the sixth and once in the seventh month of her pregnancy, each time suggesting that she would feel no pain at all at her next con-

finement. I was called December 19, 1897, at 7 P.M. I invited Professor Henry J. Garrigues and Dr. Leon F. Garrigues to accompany me, they having expressed a desire to witness a confinement under such conditions. We arrived nearly an hour later, and learned that the child had been born and the placenta expelled rapidly about half an hour before the time of our arrival. Upon inquiry the mother told us that she had felt some movements in her abdomen during the morning. At the beginning she felt these movements only once in two or three hours, but later on more frequently; sometimes they resembled the usual movements of a child, and at others they were like the cramps occuring in connection with a slight attack of diarrhea from which she had been suffering during the previous two days. At no time did she have the slightest pain, and she had no idea that labor had set in. She felt well and walked around, performing her household duties. A little before 7 P.M. she felt a great weight and pressure about the vulva, and soon after a gush of a large quantity of water occurred. On mentioning this to her husband, quite an intelligent man, he recognized her condition and told her to lie down. He scarcely had time to call and send some one to telephone for me, when the head appeared, and the husband had to assist her in the delivery. He called in a woman from the neighboring room, and when she arrived the placenta was being expelled. Throughout all this no pain whatever was experienced, simply an uncomfortable feeling. The suggestion given two months previously had acted only too well, and I was sorry not to be able to give my colleagues an opportunity to witness the efficacy of suggestion in labor.

Summing up what these cases, and others of which I have record, show, we can deduce the following: (1) That, though the sleep be not deep, enough influence can be gained to moderate or entirely banish pain. (2) That in deep sleep we can not only stop the pain, but we can by suggestion intensify or weaken the uterine contractions. (3) We can thus avoid the use of forceps in many cases in which uterine contractions have ceased. (4) That the use of chloroform can be restricted to more complicated cases of labor.

The conditions of the puerperium which can be favorably influenced by suggestion are: After-pains, lactation, peristaltic movements of the bowels, puerperal paralysis, and puerperal mania. After what has been said above it is quite obvious that suggestion may moderate or abolish after-pains, the cause of which is simply the gradual contraction of the uterus in the process of involution. In nearly all my cases the after-pains yielded to one suggestion; in some it was necessary to repeat the suggestion two or three times before they ceased permanently.

It is a well-known fact that psychic disturbances will affect lactation. Anger, sorrow, fright, and worry will change the secretion of the milk not only in quality but also in quantity, even to the extent of suddenly drying up the breasts. On the other hand, easy circumstances and cheerful surroundings will affect lactation favorably. Hypnotic suggestion acting as strongly, or sometimes even stronger, than the natural emotions, it may be made use of either to increase or decrease the secretion of the milk. In Case VI. this was especially noticeable. On the ninth day after parturition the breasts became swollen, so that they felt painful, although the milk was oozing from them in sufficient quantity to wet the patient's clothing. One suggestion was sufficient to reduce the quality of milk to the normal. It seems that the suggestion acted too strongly, for after three weeks she sent for me in order to tell me that she had only scanty nutriment for her child. I hypnotized her, and suggested that the breasts would fill within half an hour, and the quantity of the milk would continue to be more abundant. I waited for the result. I could almost see the breasts filling, and at the end of half an hour the order was complied with. She never had any trouble with the breasts again.

The peristaltic action of the intestines can easily be influenced, and sleep is readily procured by means of suggestion. Puerperal paralysis, if not dependent on cerebral hemorrhage, albuminuria, or traumatism, is amenable to suggestive treatment. Van Renterghem, Grossman, aud Vogt mention numerous cases of puerperal paralysis cured by suggestion. I have had only one case in which a puerperal paralysis of three-weeks' standing readily yielded to suggestive therapeutics. Intellectual disturbances occurring during the puerperium, as well as those that appear during pregnancy, as melancholia and mania, have been successfully treated by means of hypnotic suggestion. Ladame and Dumontpallier report several rapid cures by this method.

Many have rebelled against the biblical dictum that bearing and bringing forth of children shall be painful. Chloroform has been used to evade the so-called natural law. If I have succeeded in swelling the ranks of the rebels by pointing out a less dangerous and more pleasant means of attaining that end I shall be quite satisfied.

The Sick at Siboney.—It has been found that the convalescents in the hospital at Siboney do not recover their strength permanently, and are very apt to fall victims to a second attack of fever. It has, therefore, been decided to remove the patients from the hospitals as rapidly as they become strong enough for transportation. Of the 488 patients in the Siboney hospital, 350 are said to be in a condition which enables them to be sent home.

TOBACCO INTOXICATION, LOCALLY AND SYSTEMICALLY CONSIDERED; REPORT OF A CASE OF TOBACCO AMBLYOPIA.

BY ALBERT B. HALE, M.D.,
OF CHICAGO.

IN studying the effects of tobacco I have found not only that one must consider its general irritating properties when absorbed, but that one must reckon with its local action when sufficiently long applied. Space forbids my discussing the physiologic or local effect of acute tobacco poisoning, such as is seen in children learning to smoke, or when chewing tobacco has been accidentally swallowed, or when a tobacco poultice has been too successfully applied; nor can I dwell on the more chronic disturbances produced on the heart or stomach by the tobacco habit. I prefer to speak entirely of its effect upon the eyes, either as a local irritant to the conjunctiva or as a systemic poison causing amblyopia or a demonstrable optic neuritis.

I can best illustrate both actions by reports of cases:

J. G., twenty-three years old; for three years has

complained of redness of the eyes, with watering and itching. No refractive errors. General health good. Is occupied eight hours a day as a cigarmaker. On close examination the odor of tobacco was evident, while the dust could be seen on his clothing and in his hair. The conjunctivæ were red and injected, and there was constant lacrimation, not causing decided epiphora but enough to keep his eyes swimming in tears. I could not make a diagnosis of conjunctivitis, for there was no history leading to such an inflammation, nor were the physical signs present. It could be due to nothing but a constant irritation from the tobacco dust.

Such cases I can report by the dozen from dispensary and private practice, and my experience has been extensive enough to allow me to classify this as an "occupation disease."

As to treatment I need say little. Cleanliness, correction of refractive error when present, good air, and repeated bland washings of the eye during the day is all that can be done unless the patient will find other work. The best results have come from washes of boric-acid solution, two per cent., or of ichthyol solution, two per cent., or salve, frequent repetition of the medicine being, in my opinion, as important as the selection of the drug.

The pathology of this affection is simple. It is a continued local irritation by a foreign substance that produces and maintains an unhealthy hyperemia in the conjunctiva. Quite different, however, is the pathology of that condition known as tobacco amblyopia, which, as far as it can be explained at all, is an optic neuritis of a rather unique type. On pathologic grounds alone I was at one time skeptical about the distinctness of a tobacco neuritis. Many men even to-day, in Germany and England, deny the occurrence of such a tobacco poisoning, and claim that there must always be alcohol associated with tobacco in order to cause neuritis. Thanks, however, to Wood of Chicago and De Schweinitz of Philadelphia, we, in America can avoid this error. Still their argument is a simple one; we know that alcohol causes a definite neuritis, peripheral in some cases, affecting more the nervous trunk or the central nervous system, in others, but not necessarily restricted to one nerve, and that too, a nerve of special sense. There is, consequently, a pure alcohol optic neuritis; but why should tobacco neuritis always attack the optic nerve and no other, whenever it determines to irritate a nerve trunk? The only other nervous phenomenon caused by tobacco is functional tremor, probably a mere accompaniment of the general depression of health due to excessive smoking, yet the latest pathologic researches leave no doubt that tobacco neuritis is a true inflammatory process.

Whatever may be the logic of pathology, experience and careful examination must displace theory, and I take this opportunity of narrating such a perfectly pure case of tobacco amblyopia, with cure, that my own skepticism is overcome, and I hope that it may be as instructive to others as to myself. Cases on the border-line are not hard to find; workers in tobacco often complain of poor vision, but in them the conjunctival irritation and the unhygienic surroundings are factors, while in almost all cases of such amblyopia in public and private practice there is a history of tobacco combined with alcohol.

Mr. W., aged fifty-eight years, merchant, never smoked until he was twenty-six, when he took to Egyptian cigarettes. He persisted in the use of these for six years, smoking about ten a day. After an illness of some weeks he discovered a dislike for tobacco and ceased smoking for five years. He then began on cigars and smoked for five years. Then he stopped for six years—to 1887. Since this time, for the last ten years, he has smoked constantly —cigars—and of late has used any brand handy, smoking all day. He never touched a drop of distilled liquor in his life. In Germany, twenty-five years ago, he tried light wines, but could never acquire a taste for them. He has ordered a glass of beer every few months for company's sake, but could not drink it. In all respects he is a very healthy man, free from bad habits, and active in every out-of-door sport. He has always worn glasses, being slightly near-sighted.

In May, 1897, his sight began to fail; he first noticed that he could not see well at a distance even with his glasses, and that he was criticised for neglecting his acquaintances on the street. He remarked that when he got close to a person and tried to look directly at a face it seemed dim and cloudy. An optician of whom he had bought glasses (and this is a good example of the mischief opticians may cause by trying to correct everything in sight instead of referring patients to the ophthalmic surgeon) changed his lenses, and told him it was increasing age and that he would soon recover!

In October, 1897, I first saw him professionally, and his great complaint was that he could not see to shoot birds! His business he had given up for some time. The examination resulted as follows: Vision —right eye, 6/36; left eye, 6/18; no improvement by any lens. No astigmatism by ophthalmometer. Pupils 1½ mm., and iris refused to react to light or accommodation. To see the fundus I was obliged to dilate the pupil with scopalein, and I then saw that lens and retina were normal, the only possible disturbance being a cloudiness of one-third of the edge of the optic disc. The field of vision is illustrated in the diagrams appended.

Here then are the classical signs: (1) contracted pupil; (2) reduced vision; (3) clouded disc; (4) central scotomata for vision and colors. I at once stopped the tobacco but made no other change.

Strychnin, beginning at $\frac{1}{60}$ of a grain hypodermically was given once a day, increasing daily by $\frac{1}{100}$ of a grain until $\frac{1}{8}$ of a grain a day was reached (even this produced no physiologic effects). On this dose he was kept for five weeks. Improvement began at once on cessation of the tobacco. On November 3rd, vision (with both eyes, and with a correcting sphere of —0.75D.) was 6/15; on November 10th, 6/9; on November 26th, 6/8; on December 21st, 6/5, and from this time on he could read and write continuously and with comfort. Since then he has retained perfect vision, can attend to his business, and can see to shoot ducks better than ever. The strychnin was stopped long ago and smoking not recommenced. I am convinced that this was a pure tobacco amblyopia—a toxic tobacco optic neuritis, and nothing will ever shake my conviction.

THE EFFECT PRODUCED UPON THE BLOOD BY VACCINATION.[1]

BY JOHN S. BILLINGS, JR., M.D.,
OF NEW YORK;
ASSISTANT BACTERIOLOGIST, NEW YORK HEALTH DEPARTMENT.

COMPARATIVELY little work has been done upon the subject of the blood in vaccinia. The writer has failed to find any report of the effect produced upon the number of the red and white corpuscles of the blood by vaccination. Two observers, however, have reported the presence of foreign organisms in the blood in this condition. Pfeiffer, a somewhat unreliable observer, states in his book, published some years ago, that he has found unicellular bodies in the blood of cases of vaccinia and smallpox, and suggests these to be causally related to those diseases. Reed,[2] following Pfeiffer's observations, has studied the blood of children and monkeys before and after vaccination. He found small round bodies in the blood, from seven to ten days after vaccination, about the size of the small mononuclear leucocyte, but differing from it, however, in being granular and actively ameboid. Pale, transparent ameboid bodies of about the same size were also observed. These bodies were observed free in the plasma and were very few in number, specimens of blood being often examined for an hour before one could be found. Reed throws some doubt upon the value of these observations by stating that in one instance similar bodies were observed in the blood of an unvaccinated monkey, and he admits their presence in normal blood. Reed's article was published after the completion of the observations recorded in this report. It is possible that the writer's failure to find the bodies observed by Reed may be due to the fact that his observations of the blood were confined to the period preceding and up to the time of complete maturation of the vaccinia pustule. Reed states that the ameboid bodies noted by him are most plentiful at a later period.

The results of the examination of the blood in fourteen cases of vaccinia are here reported. Several more were examined, but only those cases are reported in which the vaccination was successful. Some of the patients were seen at the Dispensary of the Presbyterian Hospital, while the remainder were kindly sent by outside physicians. The examinations of the latter were for the most part made at their homes, some, however being brought regularly to the examiner's office. The technic was that described in the report of last year on the effect of diphtheria antitoxin upon the blood in diphtheria. At each examination fresh specimens were made and ringed with vaselin; the majority of these were very carefully examined for the bodies described by Pfeiffer and Reed, a mechanical stage being used. Dried and stained specimens (hematoxylin, safranin, etc.) were also examined to this end, but all such examinations were entirely negative. Nothing abnormal was noted; nothing even suggesting such bodies as have been described by those two observers was found.

The results of the examination of the blood in the fourteen cases will be found in the accompanying tables.

Red Corpuscles.—Vaccination seems to have no effect upon the number of red corpuscles. It is to be remembered that the limit of error with the Thoma-Zeiss hematometer is a comparatively large one, being at least 250,000 per c.cm. No changes in shape, size, or staining properties were noted in the dried and stained specimens.

Hemaglobin.—Hemaglobin, like the red corpuscles, is apparently unaffected by vaccination, no marked variation in the percentage being noted in any of the cases.

Leucocytes.—Vaccination produced a moderate but well-marked increase in the number of the leucocytes in thirteen out of the fourteen cases. In only one instance did the number of leucocytes reach 20,000 per c. mm. (Case 5). This case was interesting as showing the greatest systemic reaction to vaccination. This was probably due to the anemia and general lack of resisting power. It is well known that cases of acute suppuration in enfeebled individuals show higher leucocytosis than similar cases in strong healthy persons. As a rule, the number of leucocytes ranged at about 15,000 per c. mm. The rise took place gradually, an increase

to a point above the normal being usually first noted on the day on which the arm began to be red and tender at the point of inoculation. From this on the number of leucocytes slowly increased, reaching its maximum at about the same time as the pustule at the point of inoculation (sixth to eighth day), and falling again to normal by lysis, taking two to four days to do so.

In cases 1 and 2 the blood was examined within an hour after vaccination, in order to determine whether any preliminary decrease in the number of the leucocytes took place (leucocytolysis). None was noted, but a series of observations would be necessary to determine this point. It is unlikely that any leucocytolysis does occur, the effect of vaccination upon the system being so gradual that the usual driving off of the leucocytes into the capillaries does not occur. This view is confirmed by the experiments of Goldscheider and Jacob, who found that small quantities of bacterial toxins injected at intervals did not bring about a leucocytolysis. No changes in the morphology of the leucocytes were noted in the stained specimens. Differential counts of the various forms of leucocytes showed the increase to be in the so-called polynuclear neutrophiles, so that the leucocytosis occurring in vaccinia is one of the so-called inflammatory or pure leucocytoses, such as occur in pneumonia, suppuration, etc. Considering what a local process vaccination is, we must consider an increase in the number of the leucocytes to 15,000 per c. mm. relatively high. A local staphylococcus infection of the same extent would not give rise to such marked increase in their number.

Conclusions.—1. A moderate, but well-marked leucocytosis occurs in vaccination. It is a simple inflammatory leucocytosis, its maximum coinciding with the height of maturation of the vaccinia pustule.

2. Vaccination has no effect upon the number of red corpuscles, nor upon the percentage of hemoglobin.

3. These observations furnish no proof of the occurrence of the bodies found by other observers, and supposed by them to be causally related to vaccinia and variola.

CLINICAL MEMORANDA.

SOME UNUSUAL TUMORS OF THE ORBIT AND VICINITY.[1]

BY CHARLES STEDMAN BULL, M.D.,
OF NEW YORK.

CASE I. *Cysticercus Cyst of the Lower Lid.*—The patient was a boy, aged six years, born in New York of Italian parents, and was first seen by me at the Eye Infirmary on February 14, 1897. There was a small tumor in the subcutaneous cellular tissue, just below the lower lid on the right side, about the size of a small filbert. The skin was of normal appearance and freely movable over the tumor. The latter was smooth, non-lobulated, painless, and elastic, and looked like an ordinary fatty tumor, which was the diagnosis made. The eyes were healthy, and there was no other abnormality about the child. The tumor had been noticed about three months and had never occasioned any inconvenience, It was removed without the slightest difficulty by an incision about half an inch long, and was shelled out of its bed like a pea out of its

[1] Read at the Thirty-fourth Annual Meeting of the American Ophthalmological Society, held at New London, Conn., July 20 and 21, 1898.

pod. Two stitches closed the wound, which healed completely in twenty-four hours. The entire interest of the case centers in the microscopic examination, kindly made for me by Dr. Dixon, one of the pathologists to the Infirmary, who reports as follows:

At first glance the tumor appeared to be an echinococcus cyst, but more prolonged and careful study gave evidence in favor of its being a cysticercus cyst. The scolex was single. The hooklets were perfectly formed, and corresponded in size and number more nearly to cysticercus cellulosæ. The suction discs were more prominent than is usual in echinococcus. The original diagnosis of echinococcus was based more particularly on the character of the lining membrane of the cyst, which suggested the formation of daughter cysts. Owing to the confusion which exists among helminthologists as to the early cysticercus stages of both tænia solium and tænia echinococcus, it is difficult sometimes to reach a definite conclusion.

CASE II. *Fibrolipoma of the Accessory Lacrimal Gland.*—The patient was a boy, aged six years, whom I first saw at the Eye Infirmary on October 13, 1897. The father, who came with the patient, stated that he had first noticed a small lump on the outside of the eye near the external angle, eighteen months before, and another small lump on the corneal margin downward and inward. The first lump slowly increased in size and extended backward along the eyeball. On examination the latter was seen to hug the left eye closely in the superotemporal region, was about as large as a lima bean, flattened and colorless. The small growth on the corneal margin closely resembled an ordinary dermoid tumor, and a diagnosis was therefore made of dermoid tumor of the eyeball and orbit. The eye was normal in every respect. The tumor on the temporal aspect of the globe was removed through a conjunctival incision without much difficulty, the conjunctiva being carefully dissected away from it. The only firm point of adhesion found was at the upper and outer angle of the orbit. The cavity left by its removal was then carefully washed out and examined, but nothing abnormal was found. The conjunctiva was then carefully brought over the exposed sclera, and the wound closed by three sutures. The wound healed promptly, and the patient was discharged on the fourth day.

The tumor was examined by Dr. Weeks, the pathologist of the Infirmary, who reported that it was a fibrolipoma of the accessory lacrimal gland.

CASE III. *Dermoid Tumor of the Eyeball Complicated by a Malignant Intra-ocular Growth.*—The patient was a female infant who, when first seen, January 18, 1897, was one month old, and according to the mother's statement, was born with the existing condition of the eye. It was the mother's first confinement, and the labor was natural. The inner half of the cornea of the right eye was opaque and thickened. There was a small dermoid tumor of the eyeball in the inferotemporal quadrant, from which grew several hairs. The lower conjunctival cul-de-sac and the inner end of the lower lid were densely infiltrated, very pale, and felt like brawn. The appearance was that of a myeloid infiltration. The lens was clear and the visible portion of the fundus looked normal. The iris was dilated and did not react to light. There was neither conjunctival nor ciliary injection, nor any sign of irritation or pain, and the child seemed in excellent physical condition. Between January 18th and March 10th, there was a considerable increase in the size of the apparent dermoid tumor, and on the latter date an intra-ocular growth was made out downward and inward. By the end of March two apparent staphylomata appeared in the equatorial region, one inward and one directly downward, over which the sclera was very thin. At this time the anterior chamber was abolished, the iris lying directly against the cornea. Tension was +1, but there were no signs of irritation. The parents were advised to have the eye enucleated but refused the operation. The left eye remained healthy throughout the entire period of observation. The child remained well all through the summer of 1897, but in November the appearance of the eye had very much altered. The staphylomatous protrusions were now enormous and seemed on the point of rupture. The pupil was blocked by the intra-ocular growth, and the tension had still further increased. Sometime in December the inferior protrusion ruptured, and a mass of pigmented material protruded. A portion of this was excised and examined microscopically. It proved to consist mainly of numerous small round cells, with short fusiform cells and finely granular matter, with a few blood-vessels, the wall of the latter being made up of a single layer of endothelial cells. The outer half of the cornea still remained transparent, and there was no change in the appearance of the small, extra-ocular dermoid growth. The child was seen again in January, 1898, and although pale and anemic, seemed well. The protrusion of the intra-ocular growth had increased, and the whole globe seemed more prominent. Since then the child has not been seen.

CASE IV. *Tubercle of the Eyeball.*—The patient was a female child, aged three years, who was first seen at the Eye Infirmary on February 24, 1896. There was almost no history, and the only fact elicited from the parents was that the left eye had been red and inflamed more or less constantly for about a year. The mother was a robust Italian woman, but the father was undersized, thin, and sickly in appearance. The child was the youngest of five, all the others being apparently healthy. The patient had always been delicate, had some bowel trouble as a young infant, which lasted a long time, and has from time to time returned. The child has never walked, and speaks very little and unintelligibly; lies in a semi-stupor but can easily be roused, and frets very little. There was marked conjunctival and ciliary injection, and considerable chemosis of the ocular conjunctiva, but no swelling of the lids. The cornea was slightly hazy, but the lens and vitreous were clear. There was a yellowish reflex from the fundus, which had been noticed for several weeks. There was a staphylomatous projection in the ciliary region, and another in the equatorial region on the nasal side. The eye was divergent, apparently entirely blind, and the tension was —2. The right eye was healthy. A diagnosis was at first made of glioma retinæ, and the parents were told that the eye must be enucleated at once. The marked

marasmic condition of the patient aroused the suspicions of possible tuberculosis, and this was rather confirmed by the appearance of the father, and by the fact that two members of his family had died of chronic pulmonary trouble, presumably tuberculosis. The father had at times a chronic cough with profuse expectoration.

The eye was enucleated on March 11th, and the child recovered promptly. The specimen was examined by Dr. Weeks, the pathologist of the Infirmary, who reported as follows: The globe measured 23.5 mm. in anteroposterior diameter, 24 mm. in transverse diameter, and 23 mm. in vertical diameter. The cornea measured 10 mm. vertically and 11 mm. transversely. The globe was of irregular shape with marked protrusion on the nasal side anterior to the equator, and 4 mm. from the corneal margin. The cornea was of normal thickness and extent. The sclera was apparently ruptured at the site above described. The anterior chamber was filled with blood-clot and exudation. The iris was thickened and adherent to the lens capsule, and a portion was apparently absent. The lens was of normal size. The retina was detached and disorganized. The choroid was greatly thickened, and only traceable over part of its extent. The interior of the vitreous chamber was occupied by a relatively firm grayish mass. Microscopically, the cornea was infiltrated with small cells. In the sclera the connective-tissue bundles were separated by an infiltration of small cells. At the region corresponding with the staphylomatous protrusion the sclera was wanting. The anterior chamber was filled with old blood-clots and blood-pigment, partly broken down blood-corpuscles and fibrinous masses. It was densely infiltrated with small cells, and covered by an inflammatory pseudomembrane on both surfaces. The lens was intact. The retina was completely disorganized. The choroid and ciliary body were greatly thickened by the presence of a large number of small cells resembling leucocytes. A few of the large vessels could still be recognized. In some parts of the eye all traces of the choroid had disappeared. The mass of tissue which filled the vitreous chamber and protruded through the opening in the sclera was composed largely of leucocytes, short fusiform cells, granular detritus, and giant cells. Nodular masses were scattered here and there throughout this tissue, which had the structure of tubercle, the cells being more or less concentrically arranged at the periphery; giant cells were present, and there was some granular detritus at the center of the nodules. There were but few blood-vessels. No tubercle bacilli were found, but nevertheless the new formed tissue was in all probability tuberculous.

The patient remained in about the same condition for four or five months, and then died of what was said to be abdominal tuberculosis.

CASE V. *Sarcoma of Eyelids, Orbit, Cranial Bones, and Neighboring Cavities of Traumatic Origin.*—The patient was brought to me from a distant city, and the case is interesting because of its rarity. The patient was a boy, aged three years, whom I first saw on November 1, 1896. The parents stated that the child had always enjoyed robust health, and as yet had had none of the usual illnesses of childhood. In the preceding June (1896), while playing about the yard, he had run against a gate-post and struck the left side of his face and left eye a violent blow. There was no laceration of the skin, but extensive bruising and subconjunctival ecchymosis. The eye remained red and inflamed for about two weeks, and then slowly grew better, and nothing abnormal was noticed in the child's appearance until the last of September, more than three months after the accident. Then the eye began to protrude and became limited in motility, and the lids seemed stiff and could not be closed over the globe. When I saw the child, the exophthalmus was very marked, the protrusion being forward and outward, and the eye was almost immovable. The lids only partially covered the globe, but presented nothing abnormal. A distinct tumor could be felt on the nasal side of the orbit, as far back as the finger could reach. The media were clear and the iris reacted promptly to light, but the ophthalmoscope showed a papillitis with hemorrhages.

The parents were told that there was a tumor in the orbit, that the case was very grave, and that the eye and contents of the orbit should be removed at once. After consultation they consented to the operation, and the eye was enucleated. A growth was found filling the entire apex of the orbit, and extending along the roof and inner wall. The entire contents of the orbit, including the lacrimal gland and periosteum, were carefully and thoroughly removed, and as there was very free oozing from the bone, the orbit was tamponed with aseptic styptic cotton. The child recovered promptly from the operation, and was sent home in two weeks. Early in January, 1897, the growth returned on the inner wall of the orbit, and on the 14th a second operation was performed on the orbit and all the apparent diseased tissue was removed. At that time the neighboring cavities did not seem to be involved, and the apex of the orbit looked healthy. The child did very well for nearly two months, and then the disease again showed itself in the apex of the orbit, and the lids became infiltrated and swollen. By the middle of April the entire orbit was filled, both lids were enormously swollen and densely infiltrated, the infiltration extending in a nodular manner upon the forehead and down upon the cheek. I declined further operative interference, not only because of the rapid extension of the growth, but also because the child showed a decidedly cachectic appearance, and was much emaciated. The little patient lived until the end of July and died apparently from exhaustion, there being no head symptoms up to the end of life.

These cases of malignant disease of the orbit and bones in children, apparently originating in traumatism, are not common. The eyeball, on microscopic examination, showed the usual signs of a papillitis, but there was no trace of malignant disease found anywhere in the globe or optic nerve. The tumor of the orbit was a myxosarcoma, the bulk of the growth consisting of small, round cells, while the lids and nodules on the forehead and cheek, examined after death, proved to be sarcoma of the small-cell variety. At the autopsy the growth was found in the ethmoid cells, the sphenoid antrum, the sphenoidal and sphenopallatine fissures, and the upper nasal meatus. and the temporal and frontal bones.

REPORT OF THREE CASES OF STONE IN THE KIDNEY.[1]

By J. J. BUCHANAN, M.D.,
OF PITTSBURG, PA.;
SURGEON TO MERCY HOSPITAL.

RENAL-COLIC, bloody urine, and tenderness over the kidney are so uniformly present in cases of nephrolithiasis that one is apt to forget that renal stones exist when one, two, or even all three of these significant symptoms are lacking. The three cases here recorded illustrate this fact in varying degrees, and show that in many obscure cases the presence of kidney-stone cannot be easily excluded.

CASE I.—The patient, a man aged thirty-eight years, had enjoyed perfect health up to September 11, 1897. In particular, he had never had any trouble with his urinary organs. When he went to his work on the evening of that day he was in his usual good health. At twenty minutes past eight o'clock he was suddenly seized with vomiting and abdominal cramps, and returned to his home, where domestic remedies were applied throughout the night without effect. In the morning he summoned Dr. T. T. Kirk, his family physician, who controlled the colic with opiates, but was unable to demonstrate any abnormality by physical examination. In a few days the pain ceased but the man's temperature continued high for a week. Vomiting was present for several days. For nearly six weeks the patient was confined to bed with variable fever and constipated bowels. During this period there was no derangement of the urinary functions. On the 23rd of October he was again seized with colicky pains and his thighs were flexed on his abdomen, especially the left one. He again had fever but no vomiting. This time his urine became scanty and high colored. An enlargement was now observed in the left iliac region, beginning at the fold of the groin and increasing upward until it finally filled the left half of the abdomen. It extended from the diaphragm to Poupart's ligament.

On November 10th I saw him in consultation with Dr. Kirk. He was extremely emaciated. He had no fever. His pulse was rapid and feeble. His left thigh was flexed and the left side of his abdomen was filled by the tense, elastic mass above described. Passing perpendicularly downward in front of this mass the descending colon could be demonstrated by percussion and sometimes even by sight and touch. On November 13th at Mercy Hospital, I opened his abdomen parallel to and above the crest of the ilium. Owing to his feeble condition, the incision was made without the use of anesthesia. The cyst being exposed the incision was packed with gauze to secure an extraperitoneal evacuation. Two days later the cyst was opened with the knife and a very large quantity of clear urine evacuated. A glass drain was inserted. The man's general condition improved at once, the cyst collapsed, and one-half his urine drained through the tube. Within a few days a calculus could be felt with a probe, but repeated efforts to seize it with forceps were fruitless. Endoscopic examinations of the interior of the pelvis of the kidney were repeatedly made and satisfactory views obtained, but the ureteral orifice, containing the stone, could not be brought into the field, apparently owing to the interference of the crest of the ilium with the endoscopic tubes.

This method of locating an obstructing stone in the upper ureteral orifice to my knowledge had not been tried before, and although it was not successful in this case, it would seem to be worthy of further trials with a more favorably placed incision. Imperfect drainage and repeated manipulations caused decomposition of the urine in the sac and elevation of temperature. It was now decided to perform median celiotomy and endeavor to extract the stone from the ureter across the peritoneal cavity. Under chloroform anesthesia a median incision was made and the course of the ureter examined, in an unsuccessful effort to find the stone. Failing in this, the stone was located by forceps passed into the dilated pelvis, and bimanual efforts at its extraction made. With the left hand in the abdominal cavity and the right hand manipulating the forceps in the dilated renal pelvis the stone could be seized but not extracted, for it was grasped through the walls of the ureter and the pelvis of the kidney. Pieces of mucous membrane were repeatedly torn away, but it at length became evident that to extract the stone at any hazard would probably result in making a hole in the pelvis of the kidney and destroying the renal end of the ureter, with perhaps infiltration of urine behind the peritoneum or loss of the ureteral function. Attempts were then made to crush the stone *in situ*, which the sequel showed were successful. The celiotomy wound was closed without drainage by my assistant, Dr. Hays. Eight days later the patient had an attack of renal colic, with severe vomiting and pulse of 136. The vomiting became fecal and almost total suppression of urine occurred. His stomach was irrigated and he was given a hot-air bath. He perspired freely, his vomiting ceased, and his urine began to flow. The discharge of urine from the fistula notably diminished and an injection of methyl blue into the pelvis of the left kidney promptly stained the urine from the bladder and showed that the left ureter was again pervious. Symptoms pointing to the presence of a small stone in the bladder soon showed themselves, and later, symptoms of its passage *per urethram*. Owing to lack of observation the fragments of stone were not recovered. Four weeks from the date of the last operation the patient left the hospital convalescent, weighing 80 pounds. He is now in good health and weighs 151 pounds.

CASE II.—The patient was a boy, aged eighteen years. He never was robust; had typhoid fever four years ago. No other serious illness. The present trouble began in February, 1897. At that time, while at school, he noticed a slight, dull pain in the left loin, which in a few days was followed by a swelling in the same place. Four or five weeks later his medical attendant, Dr. Kerr of Oakdale, opened the abscess below the twelfth rib and evacuated about half a pint of pus. After the opening of this abscess his condition improved and the pain ceased and never returned.

A fistula persisted and he was sent to me for opera-

[1] Read before the Allegheny County Medical Society.

tion. The kidney was found to be very greatly enlarged and a probe which was passed through the fistula easily discovered a stone. The urine was normal in all respects. On January 18th I enlarged the opening and extracted a stone of considerable size. Two weeks later the incision was dilated with the finger and other stones extracted and the walls of several abscesses broken through. The kidney would have been removed at this second operation had the patient's condition permitted.

On February 16th the kidney was removed through the loin by an incision parallel to the last rib and extending well forward on account of the great enlargement of the organ. The operation was very difficult by reason of the universal adhesions of almost cartilaginous consistency. The kidney could not be delivered entire owing to its bulk preventing the freeing of its anterior and inner attachments. The mass was made up of a large number of abscess cavities, the largest of which were evacuated to reduce the size. Even then the mass was so large that the kidney was removed in several parts. The ureter was narrow, empty, and normal. Owing to the matting of the capsule to neighboring parts it was impossible to make a pedicle of the vessels, and, as the mass was removed, they were torn across, but fortunately, were seized with large clamp-forceps with no great loss of blood. Seven forceps were left on the vessels and the enormous cavity packed with gauze. On the fourth day the forceps were removed. Recovery was uninterrupted and the cavity remaining is no larger than a lemon. In the pelvis of the kidney removed was a large branching calculus. The existence of such a severe condition without pain, fever, hematuria or pyuria is worthy of note.

CASE III.—The patient in this instance was a man about thirty-five years of age. He enjoyed perfectly good health until about one year ago when he began to experience a dull aching in his right loin, at times extending to the testicle and down the thigh. In July, 1897, he passed a small quantity of blood in his urine. He never had renal colic. He was attended by many physicians and finally consulted Dr. N. R. Graham of Sharpsburg who made a diagnosis of stone in the kidney and referred him to me for operation. The opinion was based on the persistent dull lumbar pain and the fact that blood had been passed on one occasion.

On examination no enlargement or tenderness whatever could be discovered. There was no rigidity of the lumbar muscles. The patient was well nourished but had been unable to work for some months on account of pain. Microscopic examination of the urine showed blood-discs and pus-corpuscles. On January 6, 1898, the kidney was exposed through the usual lumbar incision and freed from its fatty capsule. It was brought into the external wound and almost its entire surface was examined by palpation and compression between thumb and finger. An indistinct resistance was felt near the pelvis. The kidney was held in the wound and an incision made from its convexity through the renal substance into the pelvis where the stone had been located. A finger passed into the pelvis through this wound encountered the stone, which was easily extracted with slender lithotomy forceps. It was flattened in shape, 5-8 of an inch in diameter, and about half as thick. A strand of gauze was packed lightly into the kidney and brought through the external wound. Hemorrhage was insignificant. The wound was closed with a single tier of silkworm-gut sutures. The wound remained aseptic, and at the expiration of four days the strand of gauze was gently removed. A smart oozing of blood followed and within an hour the loin was bulging and the patient exhibiting signs of hemorrhage. He was taken to the operating-room and chloroformed. All the stitches were taken out and the original wound laid completely open and a large quantity of clots and liquid blood removed. A Mikulicz packing was inserted and there was no more bleeding then or thereafter. The packed wound remained aseptic and the convalescence was uninterrupted. The patient is now well and has had none of the old pain since operation.

The kidney wound was not sutured primarily on account of the pus found in the urine. In a similar case this would be disregarded. Direct palpation of all surfaces of the kidney and examination by compression with the fingers is regarded as much more satisfactory than needling.

MEDICAL PROGRESS.

Enteritis with Perforation Due to the Bacillus Coli Communis.—SNELL (*Lancet*, July 30, 1898) gives an account of a case of enteric fever lasting six weeks and terminating in death, which proved a diagnostic puzzle during life and not less so at the post-mortem table, and the nature of which was not cleared up until the bacterial examination of the splenic pulp showed that it contained unmixed colonies of the bacillus coli communis. The patient was a man of good habits, aged forty-five years, who was taken sick April 20, 1898, with a sharp attack of diarrhea. He had not been feeling well for some days previously. There was malaise and slight headache, and the skin had a yellow tinge, though there was no jaundice and no fever. The tongue had a white coat. The urine was normal. May 4th there was a little fever, and this increased during the next three days until it reached 103.6° F., the highest point touched during the whole illness. It fell twice to normal, but usually ranged irregularly from 99° to 101° F. The pulse varied from 65, the normal rate for this patient in health, to 80, changing suddenly from time to time from no apparent cause. The stools were at first slate-colored and partly formed, but later in the illness they become soft and chocolate colored.

The best physicians who saw the patient gave it as their opinion that the disease was not typhoid fever, and the absolutely negative results of the serum-test supported their statement. The prognosis was considered good, as the patient was almost without symptoms, the rapid pulse alone indicating danger. This increased in the fifth week of the illness to 100, and in the sixth week to 120, and in the seventh week, that in which he died, to 140. It was at all times subject to sudden variations

in its rate without apparent reason. Toward the end of the illness there was occasionally a little pain and stiffness in the muscles of the neck and limbs, and pressure in the right iliac region was slightly painful. Three days before his death the patient's mind began to wander, and he rapidly passed into a typhoid condition.

Upon opening the abdomen, twenty hours after death, there was found to be present a purulent peritonitis, starting from three small perforations in the small intestine, twelve to sixteen inches above the ileocecal valve. The floor of other ulcers in the same region was so thin that two more perforations occurred while the intestine was being removed. The whole small intestine, with the exception of the last three feet, appeared normal. In this lower part the whole thickness of the gut was swollen, soft, and pliable, being in places almost necrotic. The lymphoid tissue was especially swollen, and the ulcers, ten of which were present, seem to start therein, but to involve, in most instances, the muscular tissue as well, and to spread laterally rather than longitudinally. The mucous membrane of the large intestine was swollen along its entire length, and was more friable than usual, but there were no ulcerations present. The mesenteric glands of the affected ileum were greatly swollen, but the other mesenteric glands were normal. The spleen was little if any larger than normal. It was rather soft. Cultures and inoculation tests made from the pulp of the spleen all developed colonies of the bacillus coli communis, and of no other bacteria, showing that this germ was present in the spleen in a pure state.

Dislocation of the Testis.—Keith (*Brit. Med. Jour.*, July 2, 1898) had a patient who was run over by a cart, the wheel passing from his left foot upward to the right anterior superior iliac spine. There was no fracture of any bone, but the scrotum was much bruised and swollen, and the right testicle could not be found. The following day, when the swelling had somewhat subsided, a hard mass could be made out just over Poupart's ligament on the right side, pressure upon which produced the testicular sensation. Gentle manipulation on several occasions failed to replace the dislocated organ, and an operation was performed for its return four weeks after the accident. The testicle was found lying in its tunica vaginalis, underneath the deep layer of superficial fascia, partly over the external abdominal ring, and partly in a rent in the external oblique tendon just above Poupart's ligament. The empty scrotum contained the remains of a small hematocele. This was scraped away, and the epididymis was carefully sutured to the lower portion of the scrotum. A small drain was placed in the lower angle of the wound, which was elsewhere closed by buried sutures. The patient made an excellent recovery, and apparently the testicle was in no wise damaged by the retention for four weeks in an abnormal position.

Fatal Fat Embolism from the Breaking of Adhesions.—Payr (*Munchen. Med. Wochenschr.*, July 12, 1898) mentions the death of a girl aged sixteen years who took ether in order to have adhesions in the right knee broken up. This was accomplished without difficulty, very little force being required, but the patient died the next day with symptoms of collapse and pulmonary dyspnea. At the autopsy the finer bronchi were found to contain a bloody, frothy fluid, and when the pulmonary tissue was examined microscopically, it was seen that the blood-vessels, including the finer arterioles and veins as well as the capillaries, were distended with embolic drops of oil. Drops of the same nature were also found in the right popliteal and iliac veins, and in the vena cava.

There have been several instances reported in which fat embolism has followed operations upon bones, but Payr could find only four cases in medical literature, of embolism following the breaking up of adhesions in joints and these were all like his own, the result of the breaking up of adhesions in the knee-joint. As the thymus gland was abnormally large in some of these patients, as well as in some who have died from fat embolism, after fractures, the question comes up for answer, whether there is any connection between the status thymicus, and the occurrence of fat drops in the blood. Payr advances the hypothesis, that inasmuch as the lymphatics are enlarged in the status thymicus, and as they may readily carry fat drops, that there is probably a causal relation between these two conditions. It must in any event be admitted that the breaking up of adhesions in patients whose bones have been rarefied and filled with fat by a long illness, is by no means a trivial undertaking; and that one ought to be especially careful in such operative attempts upon patients having the status thymicus.

THERAPEUTIC NOTES.

Cannabis Indica in Pelvic Diseases.—Labadie-Lagrave and Legueu (*Rev. de Therapeut.*, July 1, 1898) extol the use of cannabis indica in pelvic troubles in which a soothing remedy is required. It may be used with belladonna for this purpose. Given by the rectum these medicines act promptly, and so far from having a constipating affect, they rather favor a stool. In painful disorders of the ovaries, cannabis indica will not only give local relief, but will also stop the headache and feeling of restlessness which so often accompany pelvic troubles in the female. For the irregular and painful menstruation which is so often seen at the age of puberty, the cannabis indica may be administered with belladonna, with the result of reducing an excessive flow of blood and causing the pains to disappear. These drugs are equally valuable at the menopause. Some patients will tolerate only a very small dose of the belladonna.

For Intractable Eczema.—It is recommended in cases in which the application of any medicinal substance whatever seems only to increase the irritation of the skin, to cover the affected area thickly with starch powder. After forty-eight hours the crusts are removed by means of compresses dipped in sterilized water, and the powder is reapplied. Excellent results are said to be obtained by this method in very severe cases which had resisted all previous treatment.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

RED TAPE THE STUMBLING-BLOCK OF THE ARMY.

WHEN Montauk Point was selected as the location of the reception camp for the Fifth Army Corps upon its return from Cuba, an air of relief pervaded the entire country. The location of the camp seemed eminently wise; no point on the coast has such bracing air, the yellow-fever bacillus cannot live in it for a minute; the facility for procuring an inexhaustible supply of excellent water almost anywhere on Long Island is notorious, and New York City as a base of supplies is only three and one-half hours distant by train and six by water. Upon this ideal spot was to be constructed a model camp and here our wounded, sick, and exhausted soldiers should receive such tender care as would quickly nurse them back to health, and bring swift forgetfulness of the neglect and horrors they had suffered in Cuba.

It must in all fairness be admitted that the time for getting the camp ready before the arrival of the first detachment was brief. But for some apparently inexplicable reason affairs did not move forward with that despatch which characterizes the rush work, when necessary, of a private enterprise. Each department insisted that its individual work was advancing satisfactorily, but there was no harmony of action, no system, no governing mind. The result was that the work that needed to be done first was no farther advanced than that which might have been delayed to the last, and when the transports landed nothing was finished and everything in confusion.

The unfortunate consequences of all this fell upon the unhoused, poorly fed, famished, and wornout men of the ranks, as well as the sick and wounded, who, instead of having a reception, a home-coming worthy of the service they have rendered their country, were obliged to drag their gaunt and shattered frames to their designated camping ground where insufficient tents awaited them and the long familiar nauseating rations which their enfeebled stomachs were powerless to digest. And what of the sick in the hospital? The house-staff overburdened with work, the inmates suffering from exhaustion and emaciation, many of them bordering on collapse, and the supply of proper food sadly deficient. Such was the condition when the first detail of transports arrived. The second came, and the third, and still the conditions did not improve. Delicacies for the sick of every description and in great abundance, were to be had in New York, requisitions for them were made, but for some reason they were not available for the soldiers and the soldiers did not get them. The Red-Cross Society had no difficulty in procuring the desired and necessary supplies to the fullest extent of its exchequer and in distributing them to the most needy, but such supplies seemed beyond the reach of the regular army channels through which an abundant supply should have been forthcoming. In this state of affairs the Secretary of War appears upon the scene, cuts the Gordian knot of red-tape requisitioning, and the whole aspect is changed—hospital supplies and delicacies appear in abundance, the convalescents in the hospitals who are able to go home are granted furloughs of sixty days—the pressure for accommodations in the hospital is thereby removed, and the immates of regimental hospitals are transferred to the general wards —extensions to the hospitals go up on all sides, and supplies and medicines are coming in, and accommodations and proper food for the nurses are provided. Surgeon Major Brown declares that Secretary Alger did more for the camp in two days than a

hundred men not clothed with absolute authority could have done in a year. The explanation lies in a nutshell. He cut the knot of army departmental red tape.

ARMY ABUSES MUST BE INVESTIGATED.

THE neglect and incompetency which, during the recent war, have characterized the care of our troops in field, in camp, and in hospital have been fraught with direst consequences to the soldiers individually, and have been the source of grief, humiliation, and shame to the whole nation. The strong wave of indignation which is still sweeping over the country finds expression in a universal demand for a thorough and impartial investigation and the fixing of the responsibility for these unpardonable abuses. The Surgeon-General of the army petitions the Secretary of War for a Court of Inquiry, in the full confidence that its findings would relieve him and the Medical Department of the blame which has to a certain extent been charged against him. In answer to all this the Secretary of War issues a patched-up report of a whitewashing Committee of Investigation to the effect that the conditions complained of were unavoidable and no one is responsible. The Secretary goes to Camp Wikoff at Montauk Point, talks in a fatherly way to the individual soldiers, as he meets them, says he is sorry for them, and issues a furlough to every one who is ready to accept it. In a direct and authoritative way he did some good things also and left the camp in much better condition than he found it. But gratitude for a bit of personal kindness now does not excuse the criminal negligence that made that display of personal kindness possible in some instances and impossible in others, for the reason that the natural recipient of it has been needlessly sacrificed. No, Mr. Secretary, a little personal kindness done now to that camp of physical wrecks does not compensate for the great wrong that was done them at Santiago, at Siboney, and on board the transports. Some one is responsible. The hunger, the suffering, the neglect was unnecessary and, therefore, inexcusable. The country demands that the responsibility shall be established and though it may not come through a departmental investigation at your hands, Congress will probe the matter to the bottom. Perhaps it is better so; for in fixing the responsibility for the present abuses, errors of organization may be discovered that require legislative action.

EPIDEMIC CEREBROSPINAL MENINGITIS.

IT will always remain a mystery that the State of Massachusetts, which allows any one to practice any school of medicine unlicensed in any way, produces such excellent official documents as those published by its State Board of Health. Drs. Councilman, Mallory, and Wright of Harvard University have just published the results of their study of an epidemic of cerebrospinal meningitis which occurred last year in the State, and the article is in every way a tribute to the industry of these gentlemen and a matter of pride to the State Board of Health.

The authors found that the disease is most prevalent in the winter and spring, and that children and young adults are particularly susceptible to it. The disease differs from other varieties of meningitis in that the meninges of the cord are more frequently attacked, and that the nerves are more frequently involved in the inflammatory process.

The *diplococcus intracellularis* was a constant finding of the authors, who saw it only in the lesions of the disease. They believe that it enters the brain by way of the nose. Lumbar puncture, in which comparatively large quantities of cerebrospinal fluid were withdrawn, gave evidence of the micro-organism in 68.1 per cent.

In the most acute cases macroscopic examination showed little change in the vessels. Microscopic changes: injection of the blood-vessels with leucocytes in and about their walls; little fibrin present; the leucocytes always polynuclear with an intense nuclear stain. The inflammatory lesions of the brain and cord are purulent, seropurulent, and fibropurulent. The ventricles are never free, and in some of the chronic cases the surfaces of the lateral and fourth ventricles were covered with granulations. The authors found the tissues of the cord always less affected than that of the brain. There is a hyperplasia of the neuroglia cells; the cells are swollen, their nuclei large and contain masses of chromatin of varying size. The nuclei are often surrounded by irregular, branched masses of granular protoplasm. The authors found the second, fifth, seventh, and eighth nerves quite uniformly affected.

In seven of the cases there was a complicating

bronchopneumonia, in two a croupous pneumonia, and in thirteen a mere congestion with some edema. The diplococcus was found in eight cases of pneumonia. The spleen is usually not enlarged, and in uncomplicated cases the lymphatic glands were not involved. The kidneys showed acute lesions in two cases, in one of which, however, the renal disease was independent of the cerebrospinal process. Herpes was present in 31.7 per cent. of the cases, and petechiæ were found in a number of instances.

The map, charts, and magnificent plates, accompanying the report, add to the value of the scientific text. The issuance of such reports is a credit alike to its authors and to the generosity of the State which pays for it.

ECHOES AND NEWS.

Monument to Charcot.—A monument to Charcot will be formally unveiled in the Saltpétrière Hospital at Paris on October 23, 1898.

Dr. Page's Library.—The widow of Dr. R. C. M. Page of New York has presented to the University of Virginia the library of her late husband, consisting of about 650 volumes of valuable miscellaneous works.

The Next Meeting of the British Medical Association.—The next annual meeting of the British Medical Association will be held at Portsmouth, England, which city has never before had the honor of entertaining the Association. The president-elect is Dr. Ward Cozzens of Portsmouth.

Home-Sickness in the Army.—Now that the process has been begun of mustering out regiments whose services will not be required, it is reported that a wave of home-sickness is going through the camps in various parts of the country. This is said to be especially the case in the Seventh Army Corps at Jacksonville, Fla.

Yellow Fever at Franklin, La.—Dr. Carter of the United States Marine Hospital Service reported August 24th that the patient under suspicion at Franklin has developed unmistakable symptoms of yellow fever. This is the second case reported there. The people of the neighborhood continue a cordon of armed guards around the town.

Unhealthy Condition of the Volunteer Camps.—The Relief Commission estimates that there are at present 40,000 invalid soldiers in the army camps of the United States. Major-General Wheeler says that the men arriving at Montauk Point from Florida and the South are in quite as bad condition as those that come from Cuba.

Pean's Casts to Be Preserved.—Madame Pean, widow of the well-known French surgeon, has presented to the museum of the Hôpital Saint-Louis her husband's collection of 614 anatomical and pathological casts. The mold of each cast was destroyed after the cast had been exhibited and reported; hence, the collection is of high value.

American Physicians Honored.—The University of Edinburgh has conferred its honorary LL.D. upon Professor H. P. Bowditch of Harvard University and Professor William Osler of Johns Hopkins University. The University of Michigan, at its last Commencement in June, conferred its honorary degree of LL.D. upon Professor Abram Jacobi of New York.

A Fund for Medical Research.—Mr. Balfour, leader of the British House of Commons, recently delivered an address on the occasion of the distribution of prizes at the Medical School of Guy's Hospital on the subject of "Medical Research." A member of the audience became so interested in the subject that he sent an anonymous gift of $6000 for the establishment of a fund for the continuance of this work.

The Eighth Massachusetts Regiment.—In the MEDICAL NEWS, August 20, 1898, the Eighth Massachusetts Regiment was reported as being stationed near Santiago. This was an error. The regiment has been encamped at Chickamauga, and has never left our shores. Dr. J. G. Mumford of Boston says: "Nevertheless, its good state of health is notable, considering the conditions reported from that camp."

Dr. John Frederick Morse Dead.—One of the best-known surgeons of the Pacific Coast, Dr. John Frederick Morse of San Francisco, died suddenly at his home, August 21st of cerebral hemorrhage. He was a member of the San Francisco Board of Health, and a prominent mason, while as a surgeon of rare skill his fame had spread far and wide. It is said that he was the first to operate successfully for the cure of aneurism of the abdominal aorta, for which he received the congratulations of such distinguished surgeons as Czerny and Verneuil.

The Kentucky School of Medicine.—The late unpleasantness in this institution, according to Dr. Samuel E. Woody, has been carried into the courts, and has gone to the stage of a judicial decision granting an injunction against Dr. Wathen restraining him from claiming either orally or in writing to be Dean of the Faculty of the Kentucky School of Medicine, and from claiming the right to receive any mail addressed to Dr. Woody as Dean, or to the Dean of the Faculty, or to the Kentucky School of Medicine. The injunction also restrains Drs. Cochran and Boyd from claiming either in writing or orally to be professors in the school.

Suicides in the German Army.—Suicides resulting from the brutality to which privates are subjected continue to disgrace the German Army. At Ludwigsburg, a private in the Uhlans named Vögele took his life after an officer had beaten him about the head with a heavy-spurred riding boot. Several other suicides are reported this week. A private at Döbeln put the muzzle of his rifle in his mouth

and pulled the trigger with his foot; the same process was adopted by a private at Langenhennersdorf; a petty officer shot his brains out at Borna; a Hussar of the Grossenhaine Regiment put an end to his sufferings by hanging. Melancholy is the cause generally given in the official reports for these fatal acts.

Golf at the British Medical Association Meeting.—"We hope," says the *Medical Press*, "that the golf contest will henceforth become an annual feature of the British Medical Association Meeting. Golf is undoubtedly the pastime *par excellence* for medical men. All the petty annoyances of practice and the anxieties of a troublesome case vanish under the softening influence of the drives, approach shots, and skilful long puts. The idea, therefore, of bringing together the devotees of the game at the Edinburgh meeting was a happy one. Contests were arranged between residents in Scotland and the rest of the world. Of course, the Scotchmen were skilful, and the serious beating that the "rest of the world" received was not calculated to create a favorable impression of the progress of the game outside the borders of the country which gave it birth."

A New Question of Responsibility in Connection with the Army.—The routine methods of peace are not adapted to emergencies in times of war. This finally dawned upon the War Department, and on August 10th an order was issued from the Adjutant-General's Office permitting certain surgeons to draw upon a special fund for delicacies for the sick regardless of departmental routine. This was sent to the Surgeon-General for transmission to the designated authorities. It read as follows: "Medical officers in charge of general hospitals, hospital trains, hospital transports, and hospital at the camp at Pablo Beach, Fla., and at the hospital at the camp at Montauk Point, N. Y., will be allowed to expend from the appropriation, 'subsistence of the army,' for the diet of the enlisted men undergoing medical treatment under their charge, at the rate of not exceeding sixty cents per man per day for the period each is undergoing treatment. The allowance so made will constitute a special fund in the hands of the medical officer in charge, from which will be purchased the entire diet of the enlisted men while undergoing medical treatment. These purchases will be restricted to articles of food, solid and liquid, the quantities and varieties of which will be determined by the medical officer in charge. Chief commissaries of departments will transfer to medical officers in charge such subsistence funds as may be estimated for by the latter for carrying out the objects of this order." On August 25th, the War Department discovered that the Chief Surgeon at Fort Myer, Va., had not heard of the existence of the order. It is said that the Acting-Secretary of War was very indignant at the Surgeon-General when he learned this, and directed that the substance of the order be telegraphed to every chief-surgeon in charge of a general or field hospital. It was afterward learned that Surgeon-Major Wood at Montauk had a copy of the order which had been promptly received, and it is believed that all the other properly designated surgeons had also.

CORRESPONDENCE.

SOURCES OF MALARIAL FEVER.

To the Editor of the MEDICAL NEWS.

DEAR SIR: I beg to offer a few facts from observations made from 1879 to date on malaria. The theory advanced by Professor Robert Koch in the Berlin letter to the MEDICAL NEWS under date of June 25th he admits is not original, as the rôle of the mosquito had been mentioned by Bignami, Manson and Ross.

In the long years before Laveran's discovery of the malarial parasite all writers believed the poisonous material might enter the system by the digestive tract or through the lungs; by drinking contaminated water or inhaling emanations from damp and marshy places during the night and in the early morning before the heat of the sun had cleared the atmosphere. The people who lived in the marshy districts of Italy and Greece slept in the uppermost portions of their houses or on platforms raised about fifteen or twenty feet above the earth to avoid the vapors rising from the soil during the night.

In England the disease was usually ascribed to impure water, while in the United States both air and water infection were equally recognized.

At the meeting of the American Climatological Association in 1894 Dr. W. H. Daly of Pittsburg, Pa., read a paper on "Malaria a Water-borne Disease," in which he tried to prove that only the surface water is capable of producing the disease, that water from deep wells is safe and the mists arising from marshes or newly broken ground are perfectly safe.

At the meeting of the American Climatological Association in 1895 Dr. Richard C. Newton read a very interesting paper in which he admits the possibility of infection from water in some cases, but claims the majority are produced by aerial transportation. At the same meeting (1895) Dr. Thomas Darlington, Jr., of New York City read a paper on "Malaria in New York City," showing the disease to be present in various forms all over the city, sometimes traced to air infection from digging up streets, sometimes from bad water.

In the "Johns Hopkins Hospital Reports" for 1895, Nos. 1 to 5, Drs. Thayer and Hewetson give an analysis of 616 cases in "A Study of the Malarial Diseases of Baltimore" in which they state, regarding the mode of infection (page 54), that "experimentally it has been shown that while infection through the alimentary tract is improbable, subcutaneous infection is possible, as is also intrapulmonary infection."

In March, 1896, Dr. Patrick Manson delivered the Gulstonian lectures before the Royal College of Physicians of London on the "Life History of the Malarial Germ Outside of the Human Body." In these lectures Dr. Manson described the various forms found in different types of malarial disease, regarding man as an alternative host from whom they must escape in order to complete their life cycle and this condition can only be brought about by their withdrawal from the circulation of man through the agency of suctorial insects more especially mosquitoes, whose presence in malarial localities is well

known. Reasoning by analogy from his studies of the *filariæ* he thinks the plasmodia taken from man by the mosquitoes continue their development until they reach the stage of sporulation, that they then pass from the insect and are diffused in the soil or water, returning thence to man.

In the London *Lancet* for November 14 and 21, 1896, Dr. Amico Bignami of Rome, Italy, reviews at great length the work of Manson, Ross, Laveran, Celli von Fodor, and others who advocate the water or air methods of infection and suggests the bites of insects as the most plausible cause, drawing his conclusions from a study of Professor Allen J. Smith's methods of inoculating Texas fever by the cattle-tick.

At a meeting of the Section on General Medicine May 18, 1897, of the New York Academy of Medicine, I reported a series of cases of tertian intermittent which were seen in this place during February and March, 1897, during exceptionally cold weather and while the ground for many weeks was deeply covered with snow. The first patient, a woman eighty-two years old, was taken suddenly ill with severe gastric irritation, nausea, vomiting, and some paroxysms of fever; at her suggestion that "it might be malaria" I made a careful examination of the blood and found the Laveran plasmodium. A few days later her daughter, forty-nine years old, had a similar attack and the blood examination proved the diagnosis to be malaria. As the deeply driven well was found on examination to be free from taint and the family had not been away from home for several years I was at a loss to account for the disease, until my attention was attracted to a series of shelves one above another occupying all the windows and literally packed with potted plants. All the shelves were *much higher than the seats and beds which were in the rooms*. I had the rooms thoroughly cleared of all plants *and not until after this had been done* could I get results from my treatment.

A mile from these patients during the same month cases developed in two children (under similar conditions) in one family. Removal of *all* plants from the house hastened the recovery. Another case during this period in a man of thirty years could only be accounted for by the quantities of green mold covering the cellar walls under his office. He was a bookkeeper and stood all day upon a loosely fitting trap door which led into the cellar from his desk. A thorough cleansing and ventilating of this cellar undoubtedly was an important factor in his recovery.

After my experiences with these cases, and during the continuance of the cold weather, I went to some florists in localities where there were no marshes and where they were not likely to be infected by the water-supply, inquired their history, and made blood examinations. I found in four different localities people whose blood contained the malarial plasmodium. These florists were not ill but they were hardly ever quite well, complaining of digestive trouble, headache, and indefinite symptoms. They could be straightened up temporarily by a big dose of quinin.

From July, 1879, till July, 1883, inclusive, I lived in the mountains of Colorado and in each year during the spring months I saw many cases of what was called by the miners and hunters of that region, "mountain fever." This condition was undoubtedly from all the surrounding conditions and clinical evidence tertian intermittent, produced by the action of melting snow, decaying vegetable material, and sunlight. Hertz mentions a similar fever developing in the mountainous regions of Russia at the time of the melting of the snows.

During 1889-'90 I resided in Charleston, S. C. As *filaria sanguinis hominis* is endemic in Charleston I made use of sterilized water for drinking, and as I rode out into the surrounding country every clear afternoon, was careful to return early before the mists rose from the marshes. By these precautions I kept well, and frequent blood examinations gave a negative result. Later in the winter increase of work made my rides extend to a later hour in the evening, and through this exposure I contracted a sharp attack of pernicious intermittent fever with a plentiful supply of malarial parasites on each slide of blood examined. The mosquito was absent from Charleston during this time, he was not present in my experiences in Colorado, nor did I see anything of him during the winter of 1896-7 in Sag Harbor.

During the past year I have seeen many cases of tertian fever but have been entirely well. On Friday, July 15th, I spent the day at Montauk Point, returning by train at 9 P.M. I sat in my office writing until midnight, then rode home on my wheel (about one-half mile). Midway to my house the roadway is lined thickly with trees whose branches hang very low. The gardens at this point are slightly below the level of the street, very damp, and packed with flowering plants. As I rode into this section the heavy, marshy character of the air surprised me as it was so very different from anything which I had ever met here, but we have had a very wet, warm summer and I gave it but a moment's thought. On Saturday morning, the 16th, I awoke at 7 o'clock with an intense throbbing headache and intense nausea, which was followed at short intervals between 9 and 11 A.M. by vomiting of bile and watery mucus, and a slight diarrhea. At 11 o'clock I had a sharp chill lasting about twenty minutes, followed by a steady rise of temperature to 103° F. About 3 o'clock the sweating stage appeared and at 5 o'clock I felt comparatively well and had a cup of coffee and toast. During Saturday night, Sunday, and Monday I found malarial forms in my blood, but felt quite well all the week until the morning of July 25th, when I had a slight rise of temperature (101° F.) with headache and intense nausea but no chill, and was able to rise at noon and attend to my work. I took no medicine to break up the attacks, nor did I take anything in the intervals between them.

Mosquitoes are not very plentiful on this portion of Long Island and I have not been annoyed by their attempts to carry away my plasmodia.

I have ventured to intrude upon your time and space to show (1) that proper conditions will produce malarial fever even in mid-winter: *viz.*, heat, moisture, and decaying vegetable material with the mosquito absent; (2)

that exposure to the poison may be very brief and yet produce a prompt result; (3) that the mild attacks seen in this region are self-limited and may often pass away without the use of quinin or medicine in any form—simply by rest in bed and abstinence from food and drink.

Yours very truly,

J. RICHARD TAYLOR, M.D.

SAG HARBOR, N. Y., August 14, 1898.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

THE WAR DEPARTMENT'S INCOMPETENCY — HOSPITAL TRAINS FOR THE SICK SOLDIERS—THE RED-CROSS SOCIETY—PERSONAL NOTES — STATE MEDICAL EXAMINING BOARD—DR. PEPPER'S FUNERAL —HIS SUCCESSOR—A CASE OF STRAMONIUM POISONING — HEALTH-BOARD REPORT AND HEALTH STATISTICS.

PHILADELPHIA, August 29, 1898.

THE indignation felt so generally throughout the country at the gross mismanagement and incompetency of the War Department is particularly acute at Philadelphia and returning volunteers only serve to intensify the general condemnation of Secretary Alger by their stories of privation and distress. The city newspapers have been as aggressive in this respect as they have been valiant in their defense of the medical arm of the service which Secretary Alger and General Shafter seem to delight in besmirching. Of the horrible conditions existing in the various camps no better proof need be furnished than the large number of invalids among the Pennsylvania troops who went to the front well equipped materially and physically.

Dr. S. S. Cohen, having in charge the wards of Jefferson Hospital, where some of the invalids are being cared for, said Sunday that he considered every case of typhoid occurring in a modern city like Philadelphia, or in the camps of an army of a civilizated nation, an evidence of gross neglect by the authorities, and that typhoid fever being a preventable disease, deaths occurring in consequence of it are as surely murders as if the victims had been poisoned by an act of the enemy.

City Councils, so many times abused for its dilatory methods in matters of public welfare, has for once aroused itself to the occasion and already two hospital trains have been sent to the various camps to bring home sick and convalescent members of the Philadelphia regiments. Dr. Wilmer Batt, a member of Councils, secured an order from Secretary Alger permitting the men to return, a committee from Councils having agreed to guarantee all expenses, and the city hospitals furnishing physicians, nurses, sheets, blankets, etc., and the use of their wards.

The first train brought 110 men, and was composed of four hospital cars, a baggage-car fitted as medical headquarters and kitchen, and one parlor-car for the use of the physicians, Drs. Egbert and Pfromm in charge, and the nurses. The second train arrived Saturday with 57 men, Drs. de Schweinitz and B. F. Stahl having it in charge.

The Red-Cross Society will not soon be forgotten by Philadelphia's regiments, for the only comforts they received were those furnished by the Society, the receipts to date being about $10,000.

Major Lawrence S. Smith of Philadelphia, surgeon of the First Army Corps, died at sea, August 15th of typhoid fever while on his way home on the hospital ship "Relief." He graduated in 1891 from the University and served as resident physician at both the University and Pennsylvania Hospitals.

The city seems more deserted than ever, many physicians having left town this month for a few weeks' rest. Dr. H. A. Hare is at Winter Harbor, Maine, for August and September; Drs. Orville Horwitz, Louis Starr, and J. Madison Taylor are at Bar Harbor; and J. C. Wilson is traveling through Canada. W. W. Keen is in Europe. W. M. L. Coplin and E. A. Thornton have returned from "roughing it" in West Virginia.

Dr. Thomas J. Yarrow has been elected to fill the vacancy of pathologist and bacteriologist at the Samaritan Hospital.

Dr. T. H. Andrews is the recipient of a peculiar bequest in the shape of the body of an eccentric tailor who died last month directing in his will that his body be presented to the doctor. Mr. Kelly, the tailor, had various theories as to the prolongation of life by a correct diet, and for several years his food was carefully weighed and the chemical properties noted, but his theory was evidently not perfect, for he was only about fifty-five years of age when he departed this life leaving his body to science and fame.

Dr. G. G. Groff, President of the State Board of Health, returned to the city this week having gone to Porto Rico on Mr. Van Rensselaer's yacht "May," which took some seventy tons of supplies and delicacies to the army in Porto Rico, the gift of the National Relief Committee of Philadelphia.

The results of the June examinations of the State Medical Examining Board show a higher percentage of failures than ever before, 47 out of 254 applicants failing to reach the standard, a trifle more than 18 per cent. That college and State requirements are becoming more exacting each year is very evident and it must certainly, in the future, accrue to the benefit of the profession in this day of Christian-science humbugs, osteopaths, and quacks.

The funeral services of Dr. William Pepper in St. James' Church were simple but impressive. A vast throng of physicians, men of science, and laymen filled the church to overflowing, all anxious to pay honor to the dead. Drs. James Tyson and S. Weir Mitchell were two of the honorary pall-bearers, the others being representatives of the American Philosophical Society, the Free Library, the Philadelphia Museums, the Alumni Society of the University of Pennsylvania, etc. Dr. Pepper made two requests in his will concerning the disposition of his body: first, that it be cremated; second, that his brain be presented to the American Anthropometric Society of which he and the late Dr. Leidy were members. Speculation is rife as to Dr. Pepper's successor in the Chair of Practice of Medicine at the University of Pennsylvania, Dr. Osler of Johns Hopkins University, and Dr. James

Tyson being the apparent candidates, with the chances in favor of Dr. Osler.

Last week a patient at one of the city hospitals died with symptoms of exhaustion from sunstroke, but as he had not been in the hospital twenty-four hours, the coroner's physician, Dr. Cattell, held an inquest which developed the fact that death was due to the excessive use of stramonium for the relief of asthma.

That sanitary inspection of the milk-supply is bearing fruit is evinced by some statistics just published by the Board of Health, the mortality among children under five years of age for the month of July having been reduced from a total of 1485 deaths in 1897 to 1070 in 1898, notwithstanding a large increase in population. Prosecutions against milk-dealers have been followed up vigorously, and several cases of ham-poisoning which occurred last month have made the authorities more alert in the inspection of meat.

The total number of deaths occurring in Philadelphia during the week ending August 27th was 429. The total number of new cases of contagious diseases for the week was 191, as follows: Diphtheria, 56 cases with 8 deaths; scarlet fever, 17 cases with 2 deaths; typhoid fever, 118 cases with 9 deaths.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

GERMAN MEDICAL EXAMINATIONS—THE ABSENCE OF CERTAIN OBJECTIONABLE ELEMENTS SO STRIKING IN THE AMERICAN SYSTEM—ARTIFICIAL PEPTONE; A NEW FOODSTUFF — THE GERMAN BATTLE AGAINST QUACKERY AND IRREGULAR PRACTITIONERS.

BERLIN, August 22, 1898.

THE medical courses at the various German universities have drawn to a close and the vacations are on. The end of the semester came without any of that intense strain that marks the end of the medical year at an American medical school. To show that students have been in attendance up to the end of the semester their cards must be signed during the last days of July or the first of August, but cannot be signed before so that students may not arbitrarily begin their vacations some weeks ahead. But the suspense, worry, and excitement incident upon a series of examinations crowded together during the last few weeks of each scholastic year is absent. It is one of the most striking things about the close of the semester over here and one that cannot help but be a source of thought to the American medical student abroad.

If anything is clear it is that the present American system by which, especially in final examinations, all the medical branches are arbitrarily crowded into a series of examinations that all would-be graduates must pass within a period of a few weeks, is a source of untold evil and of very little practical good. A heap of undigested information is crammed by students to be retained just long enough to enable them to pass the examinations. The cramming process is, however, under present circumstances accompanied by a nervous strain at high tension that lasts for months. The waste of nervous energy involved must, if the question of an original definite store of vital energy for each individual be assumed to be true, prove an undoubted factor in shortening life. Most classes I think, however, do not have to appeal to this indefinite and not easily computable damage in general, but can often appeal to a death-roll of half a dozen members within a year or two after graduation, the mortality being the result of disease contracted during the stage of lowered resistive vitality consequent not so much upon mental overwork as upon nervous irritation and worry during the weeks preceding examinations.

Under present conditions in America it requires an act of heroic courage and supreme common sense to dare to give up the preparation for examination, because the strain of it is evidently telling upon the health. Very few have the independence of spirit to do it. On the contrary, the feverish excitement of others around him, all engaged at the same task, incites to further efforts at a time when very probably the student is already working to the top of his bent. Any one who has studied the faces of a large class of medical men during the trying times preceding final examinations cannot help but have seen the drawn, worn, tired, overdone look that settles down like a pall over faces that were so cheerful a few months before. Those who have been through the ordeal recently must look back on it as one of the most trying times of their lives.

Yet this sort of thing goes on in the face of the modern medical effort so eminently praiseworthy to make education less injurious to health. Instead of being models of what educational hygiene should be, and this might justly be demanded of them since the arrangement of all details is in the hands of *doctors*, medical examinations are probably the most unhygienic educational institution that the worship of that fetish examination as a deity, whose decision is all important, has brought down to us from medieval times.

This is not, of course, the place to discuss the subject of examinations in general, but one cannot help but express the hope that in the very near future the American medical student shall have, like his European confrère, the privilege of coming up for his examinations when he feels himself ready; that after he has spent the time required for his studies he shall not be compelled to review practically the whole of his medical teaching in a few weeks, and then willy nilly present himself for examination or wait a whole year for another opportunity.

With the spread of medical knowledge, with the acquirement of new technical methods, finally with the unwarranted invasion of the medical course by various specialties, the final examinations are becoming more and more of an ordeal. Something must be done by the faculties of medical colleges if for nothing else but as an example for other university faculties in this matter of the abuse of examinations. Medical examiners themselves, at least the conscientious ones among them, will welcome the relief from this constantly recurring yearly strain upon themselves. For that it is a serious strain upon a man who takes the work earnestly to heart no one can doubt.

For the examiners it practically cuts a month to six weeks out of their intellectual life for the year, and the time of our serious medical workers in America is too precious a heritage in the present state of American medical science to be thus needlessly squandered.

For another class of examiners, of whom perhaps the less said the better, this crowding of it all into a short space seems to mean just so much less bother for them. Such short-sighted views have prevailed too much in American medical schools.

It is time that the more deliberate, more rational, and hygienic methods that prevail in European educational matters as regards examinations should find a place in America, too. The present system is unworthy of the thoroughly advanced position of our educational methods generally, and especially unworthy of the great profession which has known so well how to solve the problems of modern hygiene satisfactorily in other respects.

The rather startling announcement that comes from one of the closing sessions of the Chemical Congress at Vienna that peptone can be manufactured artificially by a simple and synthetic process involving very little expense, has been thoroughly exploited by the daily newspapers. So far absolute confirmation from an authentic scientific source is not at hand, but the daily press account is sufficiently circumstantial to be more or less reliable, and so it is to be concluded that Dr. Leo Lilienfeld, a Viennese chemist, has really attained the much sought for goal, the synthetic production of peptone.

The process which Dr. Lilienfeld is said to have demonstrated before the Chemical Congress was a synthesis of phenol and amido-acetic acid effected by means of the oxychlorid of phosphorus as an intermediate agent. As all of these substances are extremely inexpensive, phenol being practically a derivative of waste material in the tar industry and amido-acetic acid being an ammonia derivative and easily obtained from waste products in a number of chemical industries, the new peptone, as may easily be imagined, will bear no comparison as far as cost of production is concerned, with the ordinary peptone of commerce obtained from meat. Here is of course the merit of the new discovery, the production of an inexpensive food-product.

Such a discovery is not a source of a great deal of surprise at the present moment, for the trend of practical physiological chemistry, in Germany at least, has for the last few years been in the direction of furnishing new foodstuffs at once highly nutritious and inexpensive. All the chemists of the great chemical manufactories have been occupied with the problem, and a large number of such artificially prepared foodstuffs have been put on the market. At the Congress of Hygiene in Madrid Professor Finkler of Bonn demonstrated a new product called tropon, made from plant albumen, that he hoped would prove the solution of the physiological chemical problem, a nutritious inexpensive form of almost pure albumen. The time is ripe for Dr. Lilienfeld's discovery, and the actual synthetic production of albumen would only be a fitting termination to the series of investigations that have been conducted from so many different points of view, and that have been undoubtedly so mutually suggestive to the investigators.

It remains to be seen, however, if the high hopes thus raised will be actually realized in the practical value of the new product as a foodstuff. Our chemical knowledge of albumen of the peptones and the albumoses is at best hazy. Products might easily be obtained that would answer all our present tests for peptone and yet perhaps prove unavailable for purposes of nutrition as foodstuffs. Nearly all the new artificial foodstuffs have been hailed with a blare of trumpets which seemed to indicate that a new discovery has been made but which only served to show that the firm of manufacturers which had it in hand knew the value of advertisement for its introduction.

Even before modern advertising methods came in, however, to make supposedly scientific announcements suspicious, there were hopes raised more than once only to be disappointed in the matter of inexpensive easily preserved, easily carried foodstuffs. A great chemist thought he had found in gelatin a nitrogenous substance that was destined to revolutionize the question of nutrition. Despite its seemingly appropriate chemical constitution it proved to be utterly unavailable because the elements were not in a form in which Nature could split them up for assimilation. The new product could be made tasty and filling by the addition of certain other substances but it itself passed through the system unchanged.

It is a good many years now since the gelatin episode in medical history took place, but it may serve a useful lesson as to too ready acceptance of theoretically perfect synthetic food-products in our day. The test for such an article can only be its practical value as demonstrated by actual use and the study of metabolism during its consumption. No mere chemical tests can ever replace this, and time and investigation, especially in other hands besides its inventor's, must decide the ultimate utility of the new product.

German medical men are thoroughly aroused to the duty they owe the public and the medical profession itself in the matter of the suppression of quackery. Their efforts have now reached the practical stage and airy talk has given place to active measures of suppression of the evils that exist. Each month almost sees some new step gained and, though the hydra-headed evil does not down easily, it is clear that it is but a question of a short time now until this abuse in medical matters will be practically at an end. For countries which are not so fortunate in either the vigorous union of the medical men or the hearty cooperation of their legislators and jurists the present situation in the matter of quackery in Germany is interesting.

Two new features have presented themselves of late. One is very important legally. Recent decisions of the different State courts of Germany show they have at last practically united as to the meaning of the words "secret remedies." The sale of secret remedies has been forbidden for some time, but the courts were not clear as to what constituted a secret remedy. The decisions of the Prussian courts that it is any medical preparation not prescribed by a regular physician, the ingredients and

amounts of which are not openly printed on the package in terms intelligible to the most ordinary people, are now being accepted by the courts of other German States as the interpretation of the law in the matter, and the last of the patent medicines that have been kept on the market because of the pretexts furnished by contradictory State decisions now seemed doomed to disappear.

After the matter of secret remedies comes that other abuse of branch "drug-stores" in which there is practically no responsible head, the business being run in the interests of a distant firm, sometimes by clerks of extremely limited experience and capacity. The evil has not assumed any serious proportions over here, as the apothecaries, who alone have the right of putting up prescriptions and selling remedies that require a *doctor's* prescription for their use, are under thorough regulation. The "drogueries" represent the counter opposite the prescription counter with us, where everything from the Indian panacea to Dr. X's cure-alls and tooth-brushes and bicycle lamps may be obtained. They it is principally who drive a trade in the proprietary preparations that are allowed to be sold, and it is their regulation that will make the law against secret remedies finally effective. The crusade against them has just begun here and it will be interesting to Americans, to whom the same abuses are not unknown, to watch its progress and issue.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held April 5, 1898.

THE President, B. SACHS, M.D., in the Chair.

DR. ALFRED WIENER read a report of

TWO CASES OF BRAIN TUMOR.

In the patient presented the tumor was revealed by operation; in the other, the specimen was obtained at autopsy.

CASE I.—A male, twenty years of age, was brought to his clinic in June, 1897. He was born of apparently healthy parents, but the father was alcoholic. He was a seven-months' baby, but was born apparently in a normal manner. He was slow in learning to walk and talk. When about seven years old he had otitis media, followed by a profuse otorrhea. The present trouble first announced itself while he was playing cards; suddenly the cards dropped from his hands, and his face "felt stiff." He insisted that he did not lose consciousness, and that he felt as usual by the next day. Previous to this he had suffered from frequent and severe headaches, associated with vomiting. The pain was usually frontal. One month after the attack just described, there was a second and more severe attack. He remained dazed for about two hours; speech was slow, and he could express his thoughts only with difficulty. He slowly became weaker, and vision failed. When first examined there was no perception of light in the right eye; with the left eye he could see fingers at four feet; the pupils reacted to light; the veins were engorged; the disk was swollen and hazy. The tongue was protruded straight. The dynamometer showed marked loss of power on the right side. The patellar reflexes were absent on both sides. There was motor aphasia. Physical examination showed the heart, lungs, kidneys, and spleen to be normal, and the blood examination revealed a leucocytosis. There was increased excitability on the right side to the electric current. The boy appeared fairly well nourished, but was distinctly apathetic. Smell and taste and muscular sense were unimpaired. These symptoms pointed to a tumor. Abscess was excluded for the reason that there was no source of infection. The history was negative regarding tubercular and syphilitic infection. He had been unwilling at first to venture upon the diagnosis of the location of the neoplasm. The possibility of multiple tumors was borne in mind. After four weeks the reflexes in the lower extremities began to return. The headaches became more severe and the disturbance of speech more positively that of motor aphasia. He had therefore come to the conclusion that the tumor was a cortical one, involving the face and arm centers and the posterior extremity of the third frontal convolution—*i.e.*, the speech center. During this time the man had been on antisyphilitic treatment, but with negative results. The slow growth of the neoplasm led him to believe it was a glioma. An operation was advised because he was reasonably sure of the location of the growth, and because a trephine operation seemed justifiable even if the tumor could not be removed.

The patient was operated upon by Dr. A. G. Gerster on July 31st, but the operation through the scalp and skull was attended by such great loss of blood that further interference was postponed. A few days later the operation was resumed by Dr. H. Lilienthal. A piece of the tumor was removed and proved on microscopical examination to be a telangiectatic glioma. Any attempt at manipulating it resulted in severe hemorrhage. Some days after the operation a small abscess was found near the surface, and this was incised and evacuated. After this improvement was more manifest. On October 12th, it was noted that the patient was irritable, and at times, quite excited. He showed some ataxia in his movements; the speech was distinctly hesitating; the patellar reflexes were present, but much diminished. His muscular sense was still present. On November 1st another localized abscess was detected and evacuated. The tumor has been steadily growing out through the wound. On January 18th it was noted that the patient could no longer express the names of familiar objects. On January 28th the mass measured 4¼ inches in length, 2¾ in width at the upper portion, and 3¼ inches at the lower part. On February 8th, when he was just recovering from an attack of influenza, it was found that he could no longer walk alone, and that he was much slower of comprehension than formerly. On February 23d the tumor measured 5 inches in length, 3 inches in width at the upper portion, and 3¼ inches at the lower portion. During the month of March he became more apathetic and could not repeat his own name. At the present time there is paresis of the left facial and right upper and lower extremities; the patellar reflex is present on both sides; there is double abducens palsy,

more marked in the left eye; there is still a tendency to fall toward the right side and backward. The muscular sense on the right side is very much affected. The tumor now measures 5 inches in length, 3¼ inches in width at the upper part, and 3½ inches at the lower part. There have been no severe headaches or epileptic seizures. It is probable that the tumor has been growing just as extensively within the skull as on the outside. The forced laughing, the double abducens palsy and the aphasia all point to extensive involvement of the cortex by the growth.

CASE II.—A boy, aged seven years, seen first October 19, 1897. The child was born of healthy parents, but the father was alcoholic. The patient was the second child and was born after a normal labor at full term. He was perfectly well up to twenty months old, at which time he apparently had an attack of rheumatism, lasting five weeks. From then up to a short time before coming under observation he was well developed, both physically and mentally. It was then noticed that he went down stairs clumsily. About this time he came home one day with a marked swelling over the right frontal and parietal region, and said that a man had struck him with his fist over this part of the head. After this he suffered from severe headaches, and about the same time it was noticed that he was not as bright as formerly. It was next noticed that fluids would run out of his mouth while he was drinking. On October 19th examination revealed a paresis of the two lower branches of the right facial nerve without any electrical change. The tongue when protruded deviated toward the right. There were analgesia and slight dulness to touch on the right side of the face. The patellar reflexes were absent on both sides. There was no bladder or rectal trouble, and there has been no epileptic seizures. Although appearing distinctly apathetic he was fairly intelligent. There was also a double optic neuritis. No evidence of syphilis or tuberculosis could be found. Abscess was excluded for the same reason as in the first case. On account of the complete hemiparesis and hemianesthesia, without loss of the muscular sense, the tumor was thought to be subcortical and located near the internal capsule. The tumor was suspected to be a glioma on account of the location and the symptoms. He was put upon antisyphilitic treatment. On October 23d the patellar reflexes were found to be present but very much diminished, and anesthesia was more prominent, especially in the right upper extremity. On November 11th the optic disks on both sides showed marked atrophy and small hemorrhages could be seen in the retina. He walked with a distinct hemiplegic gait. On November 16th anesthesia was quite marked in the hand and face and the right arm was totally paralyzed. Up to December 2d the condition remained about the same. The patellar reflexes were exaggerated on both sides. On account of the extensive paralysis of the arm and face and slight involvement of the leg he had been inclined to believe that the greater part of the tumor occupied the centrum ovale. The antisyphilitic treatment had been given a fair trial without the slightest improvement. On January 20th, having recovered meanwhile from an attack of scarlet fever, it was found that there was spasticity on the paralyzed side, that he was unable to walk, and was totally blind. On February 7th he died, having been intelligent to the last moment. The autopsy was made by Dr. Wiener four hours later. The abdominal and thoracic organs were normal. The brain weighed fifty-two ounces. The convolutions over the left hemisphere were very much flattened. The left hemisphere was decidedly softened, and horizontal sections through it revealed a soft, infiltrating tumor occupying the entire centrum ovale. In the lower portion of the hemisphere the tumor was mainly frontal. The microscopical examination showed it to be a gliosarcoma.

Dr. Wiener said that the absence of the patellar reflexes had been reported by others, but no satisfactory explanation had been offered for this phenomenon up to the present time. Frontal ataxia, which was really due to involvement of the trunk muscles, which have their location in this particular portion of the brain was another interesting point. It was worthy of note that in both cases the father was alcoholic. In the second case as there was one symptom present before the trauma, he was inclined to believe that the trauma only served to make the pathological condition manifest. The relief afforded by the trephining was evident in the first case.

DR. C. L. DANA said that in the specimen he noticed a portion of the tumor lying back of the Rolandic fissure. This, he thought, might explain the ataxia He had recently seen a large abscess of the frontal lobe in which there had been no history of ataxia. It seemed to him straining the point to try and make it a frontal ataxia. It could not be from the involvement of the trunk muscles.

DR. J. ARTHUR BOOTH said that in the three cases of frontal tumor that he had seen there had been no ataxia and the reflexes had been absent after the symptoms had been well developed.

DR. JOSEPH FRAENKEL said that he was convinced that the condition of the knee-jerks was entirely dependent upon the contraction of the muscles. Another factor, of course, is the muscular sense, and still another is the difficulty of determining clinically slight disturbances of deep sensibility. In the case under discussion he would explain it by invasion of the frontal and parietal lobes, and the probable more or less marked disturbance of the deep sensibility.

DR. W. M. LESZYNSKY said that the more he tested the knee-jerks the more he thought the theory of inhibition could be, to a great extent, sustained. This had been particularly noticeable in cases of meningitis in children that he had observed in the early stages. These children had been previously tested for their knee-jerks as a matter of routine. When the signs of pressure had set in later the knee-jerks had become exaggerated, and this he attributed to the irritation within the brain. A similar explanation could be offered in connection with the case now under discussion.

DR. B. SACHS thought the question of ataxia in these cases could not be settled by the supposition that it was wholly due to the invasion of the tracts lying in the

vicinity of the parietal lobule, for the reason that ataxia had been noted in other cases of frontal tumor in which there had been no involvement of that particular region. It seemed to him, therefore, that the ataxia had come to be looked upon as a symptom of frontal tumor. The behavior of the reflexes in the cases reported seemed to him very remarkable. In his own mind the older theories were of greater help than the theory suggested by Van Gehuchten, or that propounded by Dr. Fraenkel. He believed Dr. Fraenkel was confounding things which are coincident, without necessarily being related, as cause and effect. It would not do simply to assume that there were changes in the deep sensibility which we were as yet unable to detect clinically. He was inclined to believe that the same causes which produce loss of reflex are also responsible for the changes in the tonus and in the deep sensibility. There was probably some additional fact in the explanation of the reflexes which was yet lacking, but we should not endeavor to make the facts fit the theory. Another interesting point in this case was the certainty with which it was diagnosticated as a subcortical tumor. The hope of an excision had been abandoned at a very early day. The diagnosis of its situation had been largely based upon the non-occurrence of epileptiform seizures from the beginning to the end of the disease.

DR. WIENER, in closing, said in reply to Dr. Dana, that he did not doubt that there might be tumors of the frontal lobe without any ataxia, but it had been shown that when the portions bordering on the frontal convolutions were destroyed there is this peculiar cerebellar gait. If Dr. Fraenkel's theory regarding the reflexes was correct he could not understand why, in the cases just reported, the reflexes should have returned afterward. He thought the increased reflexes were due to the destruction of the normal inhibitory influence.

A CASE OF SUBCORTICAL VISUAL APHASIA.

DR. JOSEPH COLLINS reported such a case, and presented the brain. The patient, a male, fifty-eight years of age, had not had syphilis, rheumatism, or gout, nevertheless the vessels showed well-marked arterial sclerosis. For five months he had been complaining of headache and vertigo. Then, without warning, he became unconscious and lay in a stuporous condition for about three weeks. After this he recovered his mental balance, but was unable to return to work because, it was said, of his "weakness." Examination of the eyes showed complete right lateral homonymous hemianopsia. There was complete word blindness, and almost complete letter blindness. He could not mark a word off into syllables. There was no object blindness. He recognized things and called them by their right names. He wrote very badly to dictation, and it showed that he could not retain the words in mind long enough. When asked to read what he had written, he pointed to each word, and said: "I would like very much to read," and continued to repeat this again and again. He did not give the slightest heed to words put in writing, although he responded promptly to spoken commands. Spontaneous speech was not materially disordered. The symptoms pointed to a lesion between the angular gyrus and the visual centers, situated in the posterior end of the left hemisphere. If the lesions were in the primary visual center, there would be object blindness.

The patient had been admitted to the City Hospital, and extended observation showed no material change in the above findings. He was easily excited. On November 8, 1897, he suddenly fell over in a general convulsion. He did not recognize any one after that, and soon developed a right-sided hemiplegia. The autopsy was made a few hours after death. There was no noticeable abnormality aside from the brain, except an extensive arterial sclerosis. The entire occipital lobe was reddish-yellow, and with the exception of the extreme posterior cortex, the brain was replaced by a cystic formation. Nearly all of the lingual gyrus and the cuneus had been destroyed—in short, the cystic formation involved the whole posterior part of the left hemisphere save the very apex of the cuneus, and particularly the inner surface. The remainder of the left hemisphere was apparently normal. The temporal lobes were not implicated. The depth of the lesion was almost through the entire thickness of the white matter, and into the ventricles. Both lateral ventricles were distended with clots.

REVIEWS.

OPERATIVE GYNECOLOGY. By HOWARD A. KELLY, A.B., M.D., Professor of Gynecology and Obstetrics in the Johns Hopkins University; Fellow of the American Gynecological Society, etc. With Twenty-four Plates and over Five Hundred and Fifty Original Illustrations. In Two Volumes. New York: D. Appleton & Co., 1898.

THIS work of Dr. Kelly, not only marks a distinct innovation in the conventional form of medical book-making, but also sets a high standard for all future text-books in this specialty. The distinctive feature of the book and one that impresses the reader upon first glance and grows more and more satisfying as familiarity with the work advances, is the great excellence and abundance of the illustrations; indeed, the first half of the first volume abounds in illustrations to such a degree that the text drops into a minor position. The illustrations are almost exclusively made from original drawings and, to the operating surgeon and the practical anatomist, bear evidence upon their face of being perfect reproductions from the living or dead subject; and, not only this, they are distinctively works of art.

The author's aim in writing the book, as announced in the preface, has been to place in the hands of the many friends, who, from time to time, visit him and follow his work, a convenient summary of the various gynecological operations he has found best in his own practice. The work is not, as had been generally expected, a digest of the literature of the subject but a record of the author's own personal work, and a description of operations as performed by himself. It must not be inferred, however, that he has confined himself, in this regard, to those particu-

lar features of the specialty in which he has done original work or prosecuted special research. In the two volumes the entire realm of gynecological procedures is pretty thoroughly embraced.

This is distinctively a work upon operative gynecology, and it is interesting to note that in the chapters the subject has been classified in accordance with the operative procedure described. In contrast to this are many recent gynecological books in which the subjects are classified in accordance with symptoms. It has been so long the custom in works on general medicine, to base the classification of the subjects upon the pathology of disease, that this recent marked departure from the custom of standard works implies a degree of uncertainty in pathology. This is not to be wondered at when we realize that at the present time we are passing through a transition stage, not only in pathology but also in therapeutics. Symptoms, we are sure of, and of surgical procedure there can be no doubt.

Dr. Kelly's original investigation into the subject of treating by operative procedure retrodisplacements of the uterus, his advocacy of suspension of the uterus by intraperitoneal bands, as well as his original method of investigating and treating diseases of the bladder, ureters, and kidney, have all been thoroughly presented in current medical literature, but they naturally form a very important part of the work under consideration. In lacerations of the perineum and relaxation of the vaginal outlet, Dr. Kelly follows literally the improved Emmet operation and illustrates it by elaborate and clear illustrations. It is, at best, a complicated procedure, and simpler methods are known to produce equally good, if not better, results.

It is somewhat of a surprise to find in so pretentious a work as this, and one destined to be more or less of a standard authority, indorsement and even advocacy of the teaching that the normal vermiform appendix can be palpated with certainty through the abdominal walls. The limited number of cases in which this is possible would certainly prohibit its introduction. The statement on page 481, that it is unjustifiable to attempt to dilate a cervical canal sufficiently to permit the introduction of the index-finger into the uterine cavity, will not meet with universal acceptance, nor discontinue that practice among men whose custom it is to resort to this procedure for the purpose of exploring the interior of the uterus with the finger.

As might be expected, the principal effort in the book has been expended in describing and illustrating surgical procedures. The author shows most careful study in investigating the cause of complications attending the recovery from surgical operations, but comparatively little attention is given to the etiology of original pathological conditions. The author is an ardent advocate of conservative surgery, especially of myomectomy in preference to hysterectomy for uterine tumors, and of the various conservative procedures recommended for preserving the healthy portions of the ovaries and Fallopian tubes for the purpose of continuing to the woman her menstrual experiences and securing for her, as far as possible, the possibilities of conception.

The few criticisms offered here are of minor importance. The book itself is a monument to the indomitable energy, devoted scientific spirit, and unsurpassed surgical skill of its author, and, in doing credit to him, honors likewise American gynecology and American surgery.

THERAPEUTIC HINTS.

For Chronic Laryngitis in Children.—

℞	Ac. hydrochlorici dil.	ʒ i
	Aluminis	ʒ iss
	Mellis	℥ i
	Aquæ	ʒ v.

M. Sig. Use as a gargle every four hours.

For Erysipelas.—Apply the following ointment, covering with a roller bandage, or with a mask if the disease affect the face:

℞	Ichthyol	ʒ iiss–v
	Petrolati	gr. lxxx
	Lanolini	ʒ iv.

M. Ft. ungt. Sig. External use.

For Chronic Bronchitis.—

℞	Apomorphinæ hydrochlorat.	gr. ss
	Syr. pruni virginianæ	℥ ii
	Syr. picis liquidæ	ʒ iv.

M. Sig. One tablespoonful three times a day.

To Relieve the Pain of Ocular Neuralgia.—For this purpose MARKOFF considers morphin and cocain inadequate and recommends cyanid of potassium or hydrochlorate of quinin. The former is used in a warm ⅓–½-per-cent. solution, of which 5–10 drops are instilled into the widely opened eye. If kept dark and cool the solution can be used so long as it retains its characteristic odor. Hydrochlorate of quinin is used in 1-per-cent. solution (dissolved without acid). It is best combined with morphin as follows:

℞	Quininæ hydrochlorat.	gr. iss
	Morphinæ hydrochlorat.	gr. ¼
	Aq. dest.	ʒ iiss.

M. Sig. Five to 10 drops for instillation. The pain is said to be entirely relieved after one or two instillations, fifteen minutes apart.

For Diarrhea of Tuberculosis.—

℞	Pulv. catechu	gr. xl
	Syr. krameriæ	ʒ i
	Tinct. cinnamomi	gtt. x
	Vini rubri	℥ iii.

M. Sig. To be taken within twenty-four hours in tablespoonful doses.—*Bricemoret.*

For Epithelioma of the Skin.—

The following plaster is recommended:

℞	Resorcin	ʒ i
	Ceræ flavæ, Resinæ aa	gr. lxxx
	Ol. olivæ	q. s.

M. Ft. emplastrum. Sig. External use.

ORIGINAL ARTICLES.

THE POST-OPERATIVE USE OF INTRAVENOUS SALINE INJECTIONS.[1]

BY EUGENE BOISE, M.D.,
OF GRAND RAPIDS, MICH.

THE five post-operative conditions which seriously endanger the life of the patient are: (1) hemorrhage, (2) shock, (3) sepsis, (4) uremia, (5) intestinal obstruction. In all of these conditions the intravenous use of saline solutions is indicated as a primary and extremely valuable factor in our life-saving efforts. This bare statement may be all that is necessary to cause mental assent on the part of this audience, though perhaps a brief review of the facts on which the assertion is grounded may be of value as aiding to bring forth corroborative facts from the large experience here represented.

I believe the intravenous route should have preference over all others because, first, by the use of a proper technic there is practically no more danger than by any other route; second, it supplies fluid to the system most quickly and most certainly; third, it brings heat directly to the cardiac and arterial ganglia; and fourth, by this method the stimulating effect of the saline solution on the heart-muscle is more immediate and more pronounced. In exceptional cases subcutaneous injections may preferably be used. It may also be well in certain cases to supplement intravenous injections with high rectal injections. But, accepting the assertion that the intravenous method is practically no more dangerous than the others, its use should be the rule, the judgment of the operator telling him when it should be aided or supplanted by one or both of the other methods. Again, I believe the solution should always be used as hot as can be safely borne—or at a temperature of 115° or 118° F. Whether the post-operative condition of the various organs is one of depression or excitation, heat as thus supplied will be beneficial. In acute anemia, whether caused by hemorrhage or the exhaustion consequent on the disease itself, raising the temperature of the fluid circulating throughout the system will aid in re-establishing physiologic activity.

In shock, in uremia, in dynamic ileus (especially if supplemented by high rectal injections), the addition of hot saline solution to the blood is beneficial. In hemorrhage, so severe as to prove fatal, though about one-half of the normal quantity of blood always remains in the body, death is caused by acute anemia of the nerve-centers. If the blood-vessels can be quickly refilled by a fluid which is not injurious to the normal blood, life will be preserved and all the organs will continue their physiologic activity. Of these solutions the normal saline solution has proven the most acceptable. It not only distends the capillaries and arterioles, but it dilutes the blood remaining in the vessels and renders it available for purposes of nutrition. It seems to exert a directly stimulating effect on the exhausted nerve-centers, and this effect is more rapidly produced and heightened if the solution is hot. André Claisse[1] thinks that the intravenous use of saline solution also exerts a direct hemostatic influence, aiding in the formation of a clot at the point of hemorrhage.

Many patients present themselves for operation in a condition somewhat resembling that brought about by an acute hemorrhage. In other words, emaciated, pale, with low arterial tension, and small, rapid compressible pulse, the normal volume of blood greatly lessened and the reserve of fluid stored in the system greatly depleted. Such patients are poorly prepared to sustain the further exhaustion incident to the preliminary washing-out of the bowels by free saline catharsis—as often practised—and while they will probably recover from an operation, even somewhat prolonged, the recovery will be comparatively slow and the immediate post-operative conditions of thirst and restlessness greatly aggravated. To such patients the free administration of water during the few days immediately preceding operation, and the use of a large intravenous injection of hot saline solution after the patient is anesthetized, will be of great benefit, not only in lessening the anxiety of the anesthetizer, but in allaying the discomforts necessarily consequent to the operation and in aiding the speedy re-establishment of normal physiologic functions.

In post-operative shock, a condition in no sense connected with or dependent on hemorrhage, this use of *hot* saline solution has proved one of the most valuable therapeutic measures we possess. In this condition the heart and arteries are nearly empty and the capillaries and veins proportionally dis-

[1] Read at the Twenty-third Annual Meeting of the American Gynecological Society, held at Boston, May 24, 25, and 26, 1898.

[1] *Gaz. Med. de Paris*, September 26, 1896.

tended. But this is not (as many contend) a condition of paralysis of the heart and arteries whereby the blood, by some unexplained process of natural selection, collects in the capillaries and veins instead of equally in the paralyzed arteries, but is rather one of spasm of the heart and arteries whereby the blood is forced into the capillaries and retained in the veins. In such cases the experience of operators everywhere has proved that the injection directly into a vein of a hot saline solution (118° or 120° F.) is extremely valuable. The beneficial result is not merely due to the additional fluid suddenly thrown into the system, but is largely due to the fact that the solution is hot. The heat (modified somewhat by the lower temperature of the blood) proves directly sedative to the irritated cardiac and vascular ganglia, promoting relaxation of the muscular spasm of both heart and arteries and a rapid readjustment of the circulatory conditions. To obtain the best and most rapid results it is necessary that the injection should be into a vein rather than an artery, that the hot solution may be carried to the heart and arteries as rapidly and with as little dilution as possible.

In sepsis, also, recent investigations and experiments have demonstrated the great value of intravenous injections. There are three factors which must be considered in estimating the probabilities of a fatal result in a case of sepsis: (1) the quantity of germs; (2) their virulence; and (3) the power of resistance residing in the individual. Whether the intravenous use of saline solutions meets all of these indications or not has not yet been fully determined, though numerous investigations have been made attempting to settle these questions with some degree of definiteness, and experiments on animals are continually being made along the same line. But in cases of grave sepsis that such use of saline solution is of value, testimony from an increasing number of operators in various countries, is accumulating.

Dr. Berlin of Nice[1] reports a case of septicemia following vaginal hysterectomy, in which there was great distention of the abdomen, subnormal temperature, dyspnea, and all the grave symptoms of approaching death. When death seemed imminent, he injected saline solution twice (after a short interval). At first the symptoms seemed aggravated, but improvement soon began, resulting in recovery after twelve days.

Dr. André Claisse[2] says that in infections and grave intoxications the injections are indicated. When the temperature is high, and especially when the general symptoms reveal a grave pathologic condition, this treatment should be employed in combination, of course, with the proper local treatment. He says, "As to contraindications, there are none in acute anemia or operative or traumatic shock. It is the only method of treating efficaciously a dying person. In infections the condition of the kidneys, the heart and the lungs must always be watched. . . . If the kidneys are profoundly altered and the heart weak, we must act slowly and cautiously. . . . In this treatment we have an agent which, logical in theory and based on experimentation and clinical facts, may give the most favorable results in cases which seem beyond the reach of medicines."

Lejars[1] says these injections are of the utmost value, and the great trouble is that they are not used in sufficiently large amounts. Vedel[2] in attempting to establish the value of and the indications for the use of these injections, experimented with dogs, which were first poisoned with the bacillus coli, which causes rapid death, with hemorrhages and gastro-intestinal troubles, anuria, etc. He found that recovery followed the use of these injections which first caused more or less reactionary disturbance. Also, in an alcoholic subject, with adynamic pneumonia, in whom the temperature had been elevated ten days, an intravenous injection caused, primarily, reactionary symptoms, but after several hours the temperature fell to normal and the patient recovered. The same result followed, but more gradually, in two cases of staphylococcic infection. Vedel therefore concludes: "In the infectious diseases saline intravenous injections may always be administered, but they must be practised as soon as possible after the beginning of the infection; and the important indications must be looked for in the condition of the pulse, of the blood-pressure, of diuresis, and of the general condition. Anuria and albuminuria are not contraindications."

Tommasoli of Palermo[3] reports a case of burns, so severe as to be generally considered fatal, in which saline solution was used subcutaneously several times, resulting finally in recovery in an otherwise hopeless case. In an attempt to demonstrate the actual value of these injections, as also to throw some light on their mode of action, he experimented on dogs, severely scalding them. Out of ten animals treated with saline injections, only two died, while all the control animals died within two days. Also, he found that the blood of dogs severely scalded, but not treated with serum, being injected into healthy animals caused their death unless serum

injections were given. These experiments would tend to show that an actual antitoxic influence is exerted by the saline solution, but the exact way in which this influence is exerted is not yet sufficiently demonstrated.

Roger[1] in experiments on rabbits, has shown that in animals poisoned by various toxins the intravenous injection of saline solution caused the elimination of the toxins at least one hour sooner than occurred in the control animals.

Many other experiments have been made along the same lines; but while they all show that these saline injections are of very great benefit in all cases of sepsis, the exact mode of their action has not been definitely determined. It is, of course, evident that they greatly dilute the blood and thus lessen the quantity of germs acting on the nerve-centers at any one time or place, but it would seem that they must exert influence in other directions; that they actually antagonize the toxins and increase the individual resistance. In addition to this, they certainly aid very powerfully in eliminating the poison, both through the kidneys and perspiratory glands.

In those cases of partial or complete suppression of urine following operation, which so frequently result fatally in spite of our best efforts, the intravenous administration of saline solution will be of great assistance, whether the suppression is consequent on previously existing disease of the kidneys, or on conditions incident to the operation itself. Indeed, I think I am justified in saying that it is the best therapeutic agent at our command. It will, moreover, broaden our field of work in that it will enable us to operate in cases which we have heretofore avoided because of degenerative changes in the kidneys. Hare and others, by intravenous injections of saline solution, have entirely dissipated those uremic symptoms which shortly precede death in cases of chronic organic disease of the kidneys. Dumarest[2] has found intramuscular injections in cases of uremia from chronic kidney disease very efficacious. Coma began to pass away within an hour, and the toxic symptoms rapidly disappeared. He concludes that, (1) these injections are not contraindicated by renal alterations. On the contrary, they exert the best influence on the toxic symptoms due to these alterations, and even on simple albuminuria; (2) pulmonary edema and anasarca do not constitute an obstacle to this method; (3) salt water probably acts by a double mechanism, tonic and antitoxic in the beginning, which is palliative; and secondarily, eliminating, which is curative; (4) these injections are pre-eminently the proper means of treatment in desperate cases. In the last stages of uremia and eclampsia they are a most powerful agent in the struggle with death.

If intramuscular injections have proved so valuable, we can much more certainly rely on the same benefit following intravenous injections, inasmuch as the same fluid would be supplied to the system, only much more certainly and rapidly. The toxic elements circulating in the blood would be more rapidly and surely attenuated, and if there be any direct antitoxic influence it would be more rapidly exercised. Moreover, although Dumarest says that pulmonary edema and anasarca are not contraindications, we can more readily expect good results from the intravenous method, inasmuch as the vascular pressure in the kidneys is surely raised, and if they can be stimulated to renewed activity this method is the most promising. Again, in cases of ileus, so severe as to endanger life, intravenous injections will afford valuable aid. Cases are seen occasionally so severe or so advanced as to threaten certain death if not relieved by surgical means, and yet the condition of the patient is such that operation seems absolutely contraindicated.

Moltschini, at the Moscow Congress, said that in ileus fecal vomiting is generally a contraindication for operation (or in other words, when fecal vomiting occurs it is generally too late for operative interference). He also says: "The condition of the patient's strength is that on which the outcome of the operation depends, therefore weakness, collapse and intestinal paralysis are contraindications." In intestinal obstruction we estimate the condition of a patient's strength with reference to operation by the character of the pulse. In this condition there are two elements which combine to render the character of the pulse progressively bad, the first, of small importance, the removal of fluid from the system by the frequent vomiting; and the second, of much greater importance, the poisoning of the nerve centers by products absorbed from the intestines. Intravenous injection meets both these conditions, the first, by the mechanical addition of water to the blood; the second, in the way we have seen in discussing its action in other forms of poisoning, and both, by attenuating the poison and powerfully aiding in its elimination. In addition to this, it so increases the patient's power of endurance or resistance as to render operation possible in otherwise hopeless cases.

Injections may therefore be used both before and after operation with great benefit. Before, in all cases where the vitality of the patient is low, as in acute or chronic anemia, traumatic shock, especially if complicated by hemorrhage, the state of shock or

[1] *Bulletin Medicale*, December 2, 1896.
[2] *Province Medicale*, September 19, 1896.

collapse due to severe and overwhelming poisoning of the nerve-centers, as from rupture of an abscess into the peritoneal cavity, and in cases of albuminuria due to organic disease of the kidneys. They may be used with great benefit after operation in all those conditions which directly endanger life,—hemorrhage, shock, uremia, and blood-poisoning of all kinds.

As to the technic, I shall say but little. The apparatus should be as simple as possible, and yet so arranged that the temperature of the fluid can be ascertained and regulated as it passes into the vein. An apparatus, for instance, composed of two reservoirs, one for very hot and the other for cold water, emptying into a common reservoir, like an ordinary irrigating apparatus, the outflow from each to be regulated according to the heat at the lower extremity of the tube, as demonstrated by a sensitive thermometer so attached to the tube that the bulb is bathed in the solution. The part introduced into the vein should be of glass, narrow at the point like an ordinary medicine-dropper. A free incision should be made in order that there may be plenty of room. The vein should be well exposed and incised longitudinally. All air should be expelled from the tube by allowing the fluid to run through it, and the glass tube should be inserted into the vein while the fluid is escaping, care being taken that it penetrates the vein and not merely its sheath.

SURGERY OF THE PNEUMATIC SINUSES OF THE SKULL IN RELATION TO OPHTHALMIC AND AURAL SURGERY.[1]

BY ROBERT SATTLER, M.D.,
OF CINCINNATI.

To review the literature or to offer case-reports is not the purpose of this communication, but rather to give a brief synopsis of the results of personal experience with the practical surgery of the pneumatic spaces of the skull, such as fall within the scope of ophthalmic and aural surgery. Years ago I profited by the personal demonstration and teachings of Professor Zuckerkindl of Vienna. Several years after this (1882) he published in book form the results of painstaking labor under the title, "The Normal and Pathological Anatomy of the Nasal Cavity and Its Pneumatic Accessories." This anatomical treatise, with its accurate drawings and descriptions, stimulated me, as it has many others, to renewed interest in a subject concerning which there has always been much speculation, but little or no certain knowledge, and for this reason no practical surgery.

The pneumatic spaces of the temporal bone, because of their more frequent invasion by acute and chronic pathologic processes, unmistakable symptomatology and imperative necessity for surgical interference, have long before the other sinuses claimed and received the fullest recognition on the part of the general and aural surgeon. This has been owing mainly to the more ready access of this locality, the excessive suffering attending the acute cases, and the grave complications involving the meninges, as well as other dangers to life in connection with the chronic ones, for which there was relief and cure only through the medium of surgery. As a result of the painstaking labors of many in the practical field of surgery and more accurate clinical and pathological knowledge, all led and stimulated by the suggestions of Professor Schwarz of Halle, we have at the present time, for this region, a most practical and eminently successful surgery both so far as method and technic are concerned. With special emphasis, the same statement applies to the diseases and surgery of the maxillary sinuses. The brilliant achievements of dental surgery are so well known that further reference is unnecessary.

The lesions of the pneumatic spaces of the frontal, ethmoidal and sphenoidal bones are disclosed by the almost uniform presence of characteristic symptoms on the part of the walls of the orbit, its margins or contents, and even if these uncommon cases have not attracted more general attention they, nevertheless, belong to the province of ophthalmic surgery. Unfortunately these cases have not received, even from the majority of ophthalmic surgeons, the attention they deserve and only those unmistakable examples of disease in which these sinuses become the retention-cavities for pus, larvæ, micro-organisms, or tumors were the indications for rational surgery looked upon as imperative, and even in such cases, unnecessary delay was oftentimes resorted to.

Surgical interference of some kind almost forced itself upon the surgeon, unless, as not infrequently happened, he looked on until, after months of tedious suffering, fistulous openings with spontaneous evacuation of the retained contents of the choked sinuses resulted. In other instances, more successfully managed, surgery ceased with the evacuation of the contents of the distended cavities, and relief from suffering once accomplished no further interference was thought necessary. Only in exceptional cases was a more complete method adopted. This had for its object a more thorough exploration of the affected locality, and if deemed necessary, also of the adjacent sinuses, for the better diagnosis of the real nature of the disease as well as for more satisfactory irrigation, or for local treatment subsequently. My own mistakes in diagnosis and the inadequate surgical measures which I formerly adopted have fully

[1] Read before the Ohio State Medical Society.

taught me the truth of this statement. My experience leads me to say that many of the cases which are recognized as periorbitis, cyst of the orbit, caries of the margin, obstinate frontal and supraorbital neuralgias, etc., are in reality only the conspicuous manifestations of obscure chronic lesions of the frontal, ethmoidal, and maxillary sinuses.

I have seen several instances of caries of the inferior margin of the orbit in which chronic disease of the maxillary sinuses was responsible for the orbital lesions and which disappeared after an opening had been made from the mouth along the canine fossa. I remember one case in a child, of periorbitis of the lower margin of the orbit followed by caries, in which by accident, later, a fistulous opening in the mouth was discovered. This was enlarged at once along the canine fossa, pus evacuated, and the sinus drained, this procedure being followed by rapid subsidence without further treatment for the orbital lesion. I recall to mind a number of cases of periorbitis in which I was satisfied to evacuate the pus only and resort to packing and irrigation, and all were unsatisfactory. These were not cases of localized periorbitis or periostitis at all, but were really cases of frontal and maxillary sinus disease, followed either by spontaneous perforation of the bony wall, with detachment and bulging of the periorbital covering, appearing under the clinical picture of a localized periorbitis, the real nature of the disease being marked because of the latency of more positive manifestations of sinus disease of this region. In the cases similar to these an exploration of the frontal or maxillary sinuses would disclose the origin and cause for the periorbitis and caries of the margin.

Periostitis of the margin of the orbit in which traumatism can be excluded is one of the rarest lesions and in the majority of such cases the lesion is situated in one of the accessory air-cavities referred to. The so-called cysts of the orbit, in particular those met with in old persons, in which a syphilitic history and catarrhal rhinitis with polypi of the middle or superior regions of the nose are found, are not cases in which the cyst develops in the orbit but are uncommon expressions of disease of the ethmoidal cells or sinuses. The deformity in these cases resulting in displacement of the eye is marked and the periorbitis is often so tense that the presence of a solid tumor may be inferred. Another feature of these cases is that pressure against the protrusion which causes the proptosis is often followed by vertigo. The region of the anterior ethmoidal cells and the sinuses of the superior walls in the proximity of the lamina cribrosa explains this.

This was especially instanced to me in a case of extensive epithelial cancer of the orbit and pneumatic sinuses of the skull in which it became necessary to explore and open, not only the frontal and maxillary sinuses, but the ethmoidal cells and sphenoidal sinuses. In this case pulsation of the floor of the brain cavity was distinctly visible. In another case of extensive sinus disease with the growth of an exostosis within the sinus, pressure against the bony protrusion caused syncope at once. The operation in this case disclosed a large exostosis of the right frontal sinus and extensive implication of the ethmoidal cells.

Another instance of erroneous diagnosis to which I have referred is inveterate neuralgia of the frontal and infra-orbital regions. These cases are identical with those met with in the ear and referred to as neuralgia of the mastoid. Uncontrollable neuralgia of this region, when all other causes are eliminated, may be due to disease of the pneumatic cavity of the frontal or maxillary sinuses, and relief can be afforded by thorough surgery alone, *i. e.*, the opening of the sinuses, and not as is often advised and practised, by division and resection of the supra- or infra-orbital nerves.

It is the surgical method applicable to these obscure pathologic invasions of the pneumatic cavities marked by interminable chronicity and uncertain symptomatology and etiology, attended by sequences or complications which comprise a number of distinct pathological processes to which it is my main purpose to refer. Our knowledge concerning the purpose and function of the pneumatic cavities has made little or no advance. We have, however, acquired valuable practical experience concerning pathologic conditions, immediate and remote, resulting from various causes, or more accurate symptomatology, and certainly more satisfactory indications for surgical treatment. These remote sequences of chronic sinus disease comprise: fistulous openings, tortuous trails appearing in remote localities from the seat of the lesion, as for instance, on the side of the neck; as a result of a lesion in the pneumatic cells of the temporal bones, at the inner, upper, lower, and inferior margin, and even at the extreme outer margin of the orbit, as the result of disease of the frontal sinus; lateral displacement of the globe, or proptosis with formation of a firm tumor; as the result of a disease of the ethmoidal sinuses due to the retention and perforation under the periorbita of the glue-like contents of these cavities. With lesser frequency we meet with chronic empyema, hyperostosis, exostosis, periostosis, and the growth of osteophytes or exostoses; rarefaction of these cavities with dilatation, in exceptional cases, to enormous proportions; contraction of these spaces, either con-

fined to one or several, or as observed in these rare cases of leontiasis ossea affecting all alike.

The real advance and greater perfection of the surgery of the accessory cavities of the skull dates from the time that the old-fashioned drills and trepanning-instruments were exchanged for the chisel and mallet. As already stated, it is to Professor Schwarz and his followers that we are mainly indebted for the rapid and brilliant progress in that department of aural surgery which concerns the pneumatic spaces and mastoid antrum of the temporal bone and also the graver complications of middle ear disease. The more infrequent complications—sinus, thrombosis, subdural cholesteatoma, etc., etc.,—formerly unrecognized, or at least not relieved by surgical means with the same ease and thoroughness as at present, are all embraced in the scope of one of the simplest and most successful surgical methods, and its technic rendered easy and safe by the selection of the instruments referred to.

The surgery of the pneumatic spaces of the temporal bone is so thoroughly understood, and the same statement applies to the maxillary sinus, that they are referred to only because they serve as the model for the surgical treatment of the accessory cavities of the frontal ethmoidal and sphenoidal bones. My own experience prompts me to suggest and to emphasize the necessity of the same thoroughness in diagnosis and the same prompt and painstaking attention in surgical methods for these obscure lesions of the ethmoidal, sphenoidal, and frontal sinuses, both for exploratory diagnostic and curative purposes. The sinus frontalis is certainly easy of access. Many of its chronic lesions are obscure and unaccompanied by positive clinical evidences, and an exploratory operation can alone disclose the real nature of such lesions, and is certainly justified. The external opening must be preferred to the uncertain method of attempting to find the extranasal opening of the infundibulum and resort to ineffectual attempts to explore or bring about drainage along this channel. This passage can be restored far more easily from above when once a large and roomy opening into the sinus has been made from without and which at the same time gives positive information concerning its contents, dimensions, and the state of its mucous lining. The ethmoidal and sphenoidal sinuses are not so accessible, but the external method is in all operative procedures the one to be preferred to attempts to reach these cavities through the nose.

I have long since abandoned such attempts for these obscure chronic cases and rely mainly on the external operation. In every case of ethmoidal disease, I make a free incision over the frontal sinus and carry it well down on the side of the nose along the internal border of the tear-sac. The soft parts divided and hemorrhage arrested, the periosteum is detached and the tear-sac pushed to one side. The sinus frontalis is then explored, whether found normal or otherwise, its vertical depth is determined, and a point externally which corresponds to it is selected and marked. In a region between this point, which marks the floor of the frontal sinus and the upper inner border of the tear-sac, I perforate the external wall with chisel and mallet, carefully penetrating, with the inner orbital wall as a guide, in a slightly downward direction, until I reach the anterior and middle cells. With greater caution along the same course the sphenoidal cavity may be explored. I have done this but twice (exploration of the sphenoidal sinuses), once for extensive epithelial carcinoma of the orbit and face, which had withdrawn its activity from the surface structures to the accessory sinuses. All were involved and the case terminated fatally. In another case there was the most marked rarefaction of the frontal ethmoidal and sphenoidal sinuses ever found. Two weeks after the operation it required two yards of iodoform gauze, 1½ inches wide, to pack these cavities, which may convey some idea of their enormous dilatation.

THE ETIOLOGY OF YELLOW FEVER.[1]

BY FREDERICK G. NOVY, M.D.,
OF ANN ARBOR, MICH.;
JUNIOR PROFESSOR OF MEDICINE AND PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN.

THE study of the cause of yellow fever has been carried on during the past two years in South America, and as a result two organisms, isolated by two independent workers, have been described. Early in May of last year there were received at the Pasteur Institute of Paris several cultures from Dr. W. Havelburg of Rio de Janeiro. His article appeared in the *Berliner Klinische Wochenschrift* (1897) and in abbreviated form in the June number of the *Annales de l' Institut Pasteur*. A few days later cultures were received from Dr. J. Sanarelli of Montevideo. Sanarelli's first memoir was published in the June number of the *Annales de l' Institut Pasteur* (1897). This was followed in September by a second, and in October by a third, paper.

At the suggestion of Dr. Roux of the Pasteur Institute I undertook a comparative study of the organisms received from Havelburg and from Sanarelli. It was evident at the start that the two organisms were not identical, and this view was confirmed by subsequent investigations. The next step was to as-

[1] Read before the Michigan State Medical Society, Detroit, May 6, 1898.

certain which of these two organisms might be considered as the causal factor in the etiology of yellow fever. The result, it may be said in advance, was unfavorable to both. My investigations were begun in Paris at the Pasteur Institute, and have been continued on my return to Ann Arbor. It gives me great pleasure in this connection to thank Dr. Roux for his active interest, for the many valuable suggestions received from him, and for the generosity with which he placed at my disposal the unequaled facilities of the Pasteur Institute.

I. COMPARISON OF THE HAVELBURG AND SANARELLI BACILLI.

A careful comparison of the descriptions given by these two investigators will show at once that the two organisms are quite unlike. This fact is fully established on making actual, side by side, comparisons. The bacillus of Havelburg is somewhat thicker than that of Sanarelli. This difference is seen in pure cultures, and especially in stained preparations made from the animal body, as the guinea-pig. The difference is also marked in cultures on agar or gelatin grown at 16° C. They both grow singly or in pairs, and only occasionally are short threads found. A striking difference is met with in the hanging-drop examination. The Havelburg bacillus possesses active Brownian motion, and is devoid of real motility. When grown, however, on gelatin or agar at 16°, a very thick gelatinous cell-wall forms, and the organism then shows no Brownian motion. On the other hand, the Sanarelli bacillus is exceedingly motile. Few organisms, indeed, can be said to possess as active motion. The latter organism, on proper staining, shows the usual long, wavy flagella, whereas the Havelburg organism shows no such appendages. Giant whips, which will presently be described, are met with in cultures of the Sanarelli bacillus, but never in those of Havelburg.

The two bacilli stain equally well by the ordinary anilin dyes, and are not stained by Gram's method. Spore formation has not been observed in either. The indol reaction is always marked with the Havelburg bacillus, especially in cultures thirty-six to forty-eight hours old. On the other hand, the Sanarelli organism produces at most a slight trace of indol. Old agar or gelatin plates of the Havelburg bacillus have a strong amine and indol odor. Milk is coagulated or rendered decidedly ropy by the Havelburg bacillus in about forty-eight hours, but is apparently unaffected by the Sanarelli bacillus. The former, according to Havelburg, coagulates milk in about twelve hours, but apparently on cultivation this property, as in the case of other colon bacilli, is markedly diminished.

The potato-cultures show the well-known characteristics and differences observed between colon and typhoid-fever bacilli. Thus, the Havelburg bacillus, like the former, gives a thick, yellowish, or slightly brownish, rather dry growth; whereas the Sanarelli organism, like the Eberth bacillus, yields a moist, colorless, invisible growth.

On litmus-colored gelatin or agar containing glucose or lactose, at 35° to 39°C. both bacilli develop a marked acid reaction. According to Sanarelli, his bacillus slowly gives rise to an acid reaction. This was also true of the cultures when first obtained from him. Since then the organism has considerably increased its acid-producing power. Gas is produced in abundance in glucose and lactose media by the Sanarelli as well as by the Havelburg bacillus. In this respect, as well as in acid production, the two bacilli correspond to the colon group. The production of gas and acid can be observed in media when these are kept from six to eight hours at 39° C. In Uschinsky's medium[1] the Havelburg bacillus grows exceedingly well, and the growth differs in no way from that given by each of the six distinct colon bacteria that were studied at the same time. On the other hand, the Sanarelli bacillus and seven cultures of the Eberth bacillus of diverse origin failed entirely to grow. This marked difference has been repeatedly met with. In this respect, as well as in potato-culture, the Sanarelli bacillus approaches the Eberth bacillus.

A sharp distinction between the Havelburg and Sanarelli bacilli is observed when these are grown in Esmarch dishes on Stoddart's medium,[2] or in the tube medium of Hiss.[3]

Stoddart's medium has the following composition: Water, 1000 c.c.; gelatin, 5 per cent.; agar, 0.5 per cent.; pepton, 1.0 per cent.; salt, 0.5 per cent. This medium is poured into Esmarch dishes, sterilized, and allowed to solidify. The center of the medium is then *touched* with the organism to be examined, and set aside for eighteen to twenty-four hours at 35° C. Those organisms that possess motion will diffuse as a more or less transparent veil all over the surface of the medium, whereas non-motile bacteria form a small, sharp-bordered colony. Consequently the Sanarelli bacillus diffuses over the entire surface of this medium in a few hours, whereas the Havelburg bacillus shows absolutely no diffusion even after several days. The method is, therefore, of value in differentiating motile from non-motile bacteria, and may be made use of for the isolation of Sanarelli's bacillus from the organs of yellow-

[1] Vaughan and Novy, "Ptomains and Leucomains," p. 24, 1896.

[3] *Jour. of Exp. Med.*, vol. ii, p. 699, 1897.

fever bodies. It should be remembered, however, that the motile colon bacilli and the Eberth bacillus likewise diffuse. The Sanarelli and Eberth bacilli, unlike the colon bacteria, diffuse very rapidly, forming a transparent, almost invisible growth.

The tube medium of Hiss is somewhat similar in composition to that of Stoddart, and gives similar results. It contains in addition one per cent. of glucose. A stab culture is planted in the usual way and set aside at 35° C. to develop. If the organism is motile diffusion takes place, otherwise the growth is confined to the line of inoculation. If the organism produces gas an abundance of bubbles will be formed in from eight to twelve hours. The Sanarelli bacillus diffuses perfectly, and gives rise to much gas, whereas the Havelburg bacillus does not diffuse, but does give rise to gas. The colon bacilli in this medium, as a rule, diffuse readily, and gives rise to gas. The Eberth bacillus will diffuse, but does not produce gas. If this medium is colored with litmus it will serve to indicate acid and gas production as well as motility.

On Elsner's medium,[1] potato gelatin, and potassium iodid, the Sanarelli bacillus failed to grow, although repeated trials were made. The several Eberth cultures gave rise to very small typical colonies, whereas the Havelburg bacillus and the various colon bacteria grew luxuriantly. While the colon bacilli tend to spread on the surface in the characteristic manner, the Havelburg bacillus forms the usual surface pin-head colony. Under certain conditions, as will presently be shown, the Havelburg bacillus does give rise to colon-like spreading colonies.

In bouillon the Havelburg bacillus grows very readily, regardless of the reaction of the liquid. Thus, in an acid bouillon, the acidity corresponding to 20 c.c. of normal hydrochloric acid per liter, it grows just as abundantly as in the alkaline boullion containing a like amount of normal sodium hydrate in excess of the neutral point. The growth of the Havelburg bacillus, therefore, is always abundant. A thick ring forms on the glass at the surface of the bouillon, and after the lapse of a few days it takes on a yellowish tinge. The scum which forms is not even and continuous, but consists of floating masses. The liquid remains cloudy for one to two weeks, and only a slight deposit forms. Growth does not form in boullion containing 35 c.c. normal hydrochloric acid per liter.

The behavior of the Sanarelli bacillus in bouillon is, on the whole, markedly different from that of Havelburg. The growth is by no means as abundant. As a rule, no ring or scum forms. A continuous thin scum may, at times, cover the surface of the liquid, especially when the cultures are allowed to develop at about 25° C. Acid bouillon, containing 10 and 20 c.c. respectively of normal hydrochloric acid per liter, remains perfectly clear, and only a trace of deposit forms. While these two organisms show this difference with reference to acid media, they behave about alike in alkaline media. Thus, both develop in bouillon containing 50 c.c. normal sodium hydrate per liter, forming a slight growth. Neither the Havelburg nor the Sanarelli bacillus liquefies gelatin.

On gelatin plates the Havelburg bacillus presents the one characteristic which distinguishes it from an ordinary colon bacillus. The surface colony does not spread, as is usually the case with colon and Eberth bacilli, but remains as a thick convex, glistening opaque-white pin-head. The deep colonies offer nothing special; they are oval or roundish and yellow, and when ten to fourteen days old they become very dark. When the plates are several days old a strong ammoniacal, fecal odor is noticeable. As in the case of bouillon the Havelburg bacillus will grow on gelatin regardless of the reaction.

The Sanarelli bacillus, as seen above, possesses less vegetative force than the Havelburg bacillus. It will frequently fail to show the slightest growth on gelatin. This is not entirely due to the reaction of the medium. Gelatin containing 10 or 20 c.c. of normal NaOH per liter gives excellent growth in two to three days at about 18° C. In neutral gelatin the colonies are considerably smaller, and in gelatin containing 10 c.c. normal HCl. per liter the colonies are mere points. In gelatin containing 20 c.c. of normal HCl. per liter no colonies develop. The so-called typical colonies develop best at 16° to 18° C. on ten per cent. nutrient gelatin. This should not be too hard, and should have an alkalinity of about 10 c.c. of normal sodium hydrate per liter. On hard gelatin, such as fifteen per cent., and grown at 20° C., the colonies are a typical. A little attention to the temperature and to the composition and reaction of the gelatin will always enable one to obtain typical colonies. To obtain a constant low temperature a special apparatus was devised. In this running water surrounds and cools an inner compartment. By regulating the flow of the water it is possible to maintain any desirable temperature from 15° C. up to that of the room itself.

The deep colonies of the Sanarelli bacillus to the eye appear as mere white points. Under the microscope they are perfectly circular. At first they are light-yellow, coarsely granular, but in a few days they become perfectly opaque, dark brown or black in color. When grown on acid gelatin (10 c.c.

[1] *Zeitschrift für Hygiene*, 8, 159; 21, 29.

normal HCl. per liter) the colonies (atypical) do not become dark, but appear as perfectly circular, light yellow, homogeneous, wax-like bodies.

The typical surface colony of the Sanarelli bacillus appears to the eye like a droplet of boiled starch or mucus. It is thick and convex. They may be perfectly circular, but frequently will show a distinct kidney shape. An opaque, yellowish white nucleus can, as a rule, be seen at or near the center, or in case of the kidney-shaped colony at the hilus. Under the microscope the colony appears almost colorless, or with a central, light-brown tinge. It is finely granular, and the border is sharp, perfectly smooth. The nucleus is opaque, and may be round, but more often is hat-shaped, and has even been compared to Saturn with its rings. In the kidney-shaped colony the crown of the hat projects into, or is turned toward the hilus. On hard or acid gelatin only atypical colonies form. These are very small, raised points usually without the nucleus, and the kidney shape is absent.

In stab cultures in gelatin the Havelburg bacillus grows rapidly and abundantly, and the growth is like that of the colon bacillus. The Sanarelli bacillus grows more slowly along the entire line of inoculation, and there is very little tendency to spread on the surface except when the temperature is about 25° C. The growth, on a whole, resembles closely that of hog-cholera.

On agar the two organisms likewise show marked differences. In ordinary streaks on inclined agar the Havelburg bacillus (like the colon) forms at 39°C. a thick, opaque, white growth. On the other hand, the Sanarelli bacillus (like the Eberth bacillus) under the same conditions forms a thin growth, which in transmitted light is almost perfectly transparent. When cultures on inclined agar are grown at 16° C. they present an entirely different appearance. The Sanarelli bacillus forms a convex, thick, moist, slimy growth. This is perfectly homogeneous, transparent, and mucous-like in appearance. It resembles the well-known cultures of Friedlaender's bacillus. The Havelburg bacillus at 16°C. forms thick, opaque, raised growths, which show a distinct zooglea character.

When isolated colonies are obtained on inclined agar they will appear thin and transparent or thick and slimy, according to the temperature at which they develop. When developed for twenty to twenty-four hours at 39°C. the colonies are thin, flat, grayish, transparent, and circular. If they are now placed at 16° C. growth at the edge of the colony will continue, but it will take on the thick, slimy, character already referred to. In two or three days the colonies present a peculiar appearance—a thick, slimy, opalescent ring, inclosing a thin, flat area. In time the slimy growth may invade the central area and cover it up. The colony then appears as an opalescent, mucous-like drop, and eventually takes on a pearly luster. When several colonies are close together the slimy growths may coalesce and give rise to rivulets. Eventually the outer slimy border becomes transparent, and the original colony is seen as an opaque body embedded in it. This change can be hastened by placing the culture in an incubator for twenty-four to thirty-six hours.

These characteristic growths of the Sanarelli bacillus on gelatin and on agar are always obtained if the conditions mentioned are adhered to. The two extremes of temperature are necessary, as well as a distinctly alkaline medium.

Marked differences between the organisms are also observed in their effect on animals. When injected intraperitoneally into guinea-pigs 1 c.c. of the twenty-four-hour bouillon culture of the Havelburg bacillus grown at 39° C., will invariably kill in less than twenty-four hours, more often twelve to fifteen hours. The bacillus is always present in the animal in abundance. Injected subcutaneously it produces a local abscess, and the animal recovers. On the other hand, the Sanarelli bacillus under like conditions is fatal in from five to seven days, although it is possible to have cultures which will kill in less than twenty-four hours. The bacillus is present in relatively small numbers. When injected subcutaneously, unlike the Havelburg bacillus, it proves fatal. The normal serum of man, horse, rabbit, guinea-pig, etc., promptly agglutinates the Sanarelli bacillus, and has no effect on that of Havelburg.

The foregoing comparisons of these two organisms clearly indicate that they are two distinct species.

II. RELATION OF THE HAVELBURG BACILLUS TO THE COLON GROUP.

It may be well to state incidentally that this organism was isolated by injecting into guinea-pigs from 1 to 2 c.c. of the stomach contents of yellow-fever cadavers. It was present in each one of the twenty-one cases thus examined. In his published communication Havelburg called attention to the fact that his organism may be confounded with the bacillus coli communis, and that it is difficult to differentiate these two bacteria.

The distinctions between the two organisms, as laid down by Havelburg, are very slight and wholly insufficient. Thus, the Havelburg bacillus when very virulent shows the bipolar stain, whereas the colon bacillus did not show this behavior. Again, the Havelburg bacillus was non-motile, whereas the colon bacillus was said to be very motile. On gela-

tin the former gives rise to pin-head surface colonies, whereas the latter forms smooth plaques. On potato the former develops moderately, forming a grayish growth, whereas the latter gives an abundant brownish growth. Lastly, the colon bacillus is said to be less virulent than the Havelburg bacillus.

The presence or absence of the bipolar stain is of very little value in differentiating organisms. Almost without exception a bacillus when very short will, on slight staining, give a bipolar stain. The short form of the colon bacillus is no exception to this rule.

The motility of the members of the colon group, as is well known, varies considerably. While some may be exceptionally motile, there are others that are less motile, or even those that possess no motion. Some authors as Kruse (Flugge, "Die Microorganismen," 1896) proposed to designate the non-motile colon bacteria as the B. ærogenes. In other respects the ærogenes and colon group are identical. The motility of an organism is so readily influenced by unfavorable media that it is a matter of no surprise to find colon bacilli of diverse origin showing a difference in motion.

The difference observed in the growths of the two organisms on gelatin plates is such as may be expected between a non-motile and a motile organism. The ærogenes group, as a rule, gives rise to raised pin-head or drop-like surface colonies, whereas the motile colon or typhoid bacillus spreads out in the characteristic thin plaque. On growing the motile colon bacillus, under conditions which will lessen the motility, the surface colonies cease to spread and become hemispherical. The Havelburg bacillus, when grown on fifteen-per-cent. gelatin at 16° C., forms large, thin, spreading, surface colonies in size, shape, and appearance identical with the surface colonies of the Emmerich and other colon bacilli. The deep colonies likewise agree perfectly. Here, as in the case of the Sanarelli bacillus, temperature, consistency, and reaction of the medium exert a marked influence on the form of the surface colony.

The distinction between the Havelburg and colon bacilli in their growth on potato has not been verified. On the contrary, the comparison of the several cultures sent by Havelburg with six colon bacilli of diverse origin showed a marked similarity in color. A faint brownish or yellowish color was given by all. The Havelburg bacillus in general grows more rapidly than the ordinary colon bacillus, and hence the growth on potato is thicker and somewhat dryer than that of the colon bacillus.

The Havelburg bacillus would seem to be more virulent than the ordinary colon bacillus. One-half c.c. of a bouillon culture grown for twenty-four hours at 39° C. when injected intraperitoneally into guinea-pigs will, as a rule, produce death in from twelve to twenty-four hours. The ordinary colon bacillus requires a larger dose, and even this is not always fatal. On the other hand, certain varieties of colon bacillus, when recently isolated, do possess marked virulence. Thus, Emmerich[1] found that his bacillus intraperitoneally killed guinea-pigs in from eight to ten hours. Coppola,[2] studying the same organism, found that subcutaneous injections killed guinea-pigs in twelve to thirty hours. The B. cavicida of Brieger is another variety that at one time was very pathogenic to guinea-pigs.

The following experiment was made with old cultures which have been cultivated in this laboratory for ten years. The Emmerich bacillus was brought from the Berlin Hygienic Institute in 1888. The B. cavicida was obtained about the same time from Král in Prague. Full-grown guinea-pigs received intraperitoneal injections of 1 c.c. of the twenty-four-hour bouillon cultures grown at 39° C.: Guinea-pig No. 1 received the Havelburg bacillus, died in twenty-three hours; guinea-pig No. 2 received Emmerich's bacillus, died in fifteen to eighteen hours; guinea-pig No. 3 received B. cavicida, died in twenty-six hours; guinea-pig No. 4 received B. coli communis, apparently no effect even five days later. The symptoms produced in the first three were exactly alike. The rectal temperature for some time before death in all three animals was 29° to 30°. The post-mortem appearances were likewise similar. There was intense congestion of the abdominal vessels. A white, fibrinous exudate covered the liver. Considerable yellowish or bloody effusion was present in the abdominal cavity. The bacteria, alike in appearance, were exceedingly numerous on the serous surfaces.

It is evident from this experiment that the Havelburg bacillus is not more virulent than certain colon bacteria which have been kept in artificial cultivation for ten years.

On the other hand, the Havelburg bacillus, like the colon bacillus, is not markedly virulent when injected subcutaneously into guinea-pigs or rabbits. At present the injection of one c.c. subcutaneously rarely causes death in guinea-pigs. As with the colon bacillus a small abscess forms at the place of inoculation. Havelburg, moreover, states that his bacillus readily loses its virulence. This is true only to a limited extent, as seen in the above experiment.

The effects observed in guinea-pigs after injection of the Havelburg bacillus, as shown above, agree very closely with those produced by the colon ba-

[1] *Archives für Hygiene*, 3, p. 291, 1885.
[2] *Zeitzchrift für Hygiene*, 2, p. 328, 1886.

cillus. The apparent vomiting caused by the former was observed in the above experiment with B. cavicida and Emmerich's bacillus. It has also been observed by Coppola in his studies on the Emmerich bacillus. This symptom is not one of vomiting, but is rather due to lack of oxygen.

The resistance of the Havelburg bacillus is the same as that of the colon group. Comparisons between this and other organisms will be given in the third part of this paper.

The facts mentioned above, taken in connection with cultural characteristics, as described in the preceding part, clearly indicate that the Havelburg bacillus belongs to the colon group of bacteria. A careful comparison was made between the Havelburg bacillus and six colon bacilli, and the results obtained in every respect confirm this statement.

The greatest similarity exists between Emmerich's bacillus (B. Neapolitanus) and that of Havelburg. They are about the same in form and size, and are both non-motile. The cultural appearances on the ordinary media are such as to render it difficult to distinguish between the two organisms. The Emmerich bacillus, especially when grown in acid bouillon for some time, gives rise to colonies on gelatin plates, which are identical with those of Havelburg. The gelatin plates of both organisms have the same ammoniacal fecal odor. When grown on Elsner's medium, the two organisms give rise to colonies that have the same form and odor, and the surrounding gelatin in both cases is covered by a dark refracting film. Likewise the growths on Hiss' tube medium and on Stoddart's medium present the same characteristics.

It is evident that the Emmerich bacillus, which received a passing notoriety in connection with the etiology of cholera thirteen years ago, is very closely related, if not identical, with the Havelburg bacillus.

The latter may consequently be considered as a non-motile colon bacillus, modified perhaps by a more or less prolonged contact with the hydrochloric acid of the gastric juice. It follows, therefore, that the Havelburg bacillus can in no wise be considered as the cause of yellow fever.

(To be continued.)

Vacancies in the Marine Hospital Service.—A board of officers will be convened at Washington, Wednesday, November 9, 1898, for the purpose of examining candidates for admission to the grade of Assistant Surgeon in the United States Marine Hospital Service. It is desired that applications for this examination be made before November 1st. For further information or for invitation to appear before the Board of Examiners, address Supervising Surgeon-General, United States Marine Hospital Service.

WAR ARTICLES.

A TRUE PEN-PICTURE OF CAMP WIKOFF.

[Specially Reported for the MEDICAL NEWS.]

BY WILLIAM BROADDUS PRITCHARD, M.D.,
OF NEW YORK.

ARMED with numerous letters of introduction as the special representative of the MEDICAL NEWS, I visited Camp Wikoff, at Montauk Point, on Sunday last, and spent the entire day in observations and investigations regarding the general situation, and especially with reference to the health and comfort of the soldiers. My letters of introduction were in every instance acknowledged most courteously, and I was afforded every facility for observation and the acquisition of information in detail. All questions were answered frankly and without evasion, and in not a single instance within my knowledge was any attempt made to conceal or disguise the truth. So uniform and conspicuous was this exhibition of courtesy and frankness as to deserve more than mere passing mention. It affords a guarantee of the accuracy of the information obtained and the facts observed which are herewith submitted.

The Location of the Camp.—The camp stretches in scattered and detached villages of tents over several miles of grass-covered hills swept on all sides by fresh breezes from either the ocean or the sound. The grass is short and thick, and covers the earth as though with matting, affording excellent roadways, except in the valleys and in occasional brackish pools, through and across which roadways have been built. The fields and camp-streets are free from dust. The artificially-made roadways, except when the dust is allayed by sprinkling-carts, are continuously enveloped in clouds of stifling thickness, so continuous is the travel over them. The superficial soil is of rough gravel and sand. There is, according to Colonel Forwood, under this and very close to the surface a thick layer of clay of a type hygienically of great value in that it permits percolation and filtration very slowly. Under this is another layer of sand and gravel, and lower still another layer of clay. Surface-filtrations, drainage, and purity of well-water supply are ideally attainable with such conditions of soil. There is an abundant water-supply from a well equipped with a modern pumping outfit, furnishing 700,000 gallons of pure water daily, which is distributed over the entire camp by a system which is as near perfect, both mechanically and hygienically, as is possible of attainment. The camp is accessible to an unlimited base of supplies, with facilities for transportation by both land and water, the schedule time from New York City by train being less than four hours, and by boat not more than eight or ten. Such are the natural conditions present. How far they have been utilized, how far neglected and abused remains for further comment and consideration.

The Sick at Camp Wikoff.—There are about 20,000 troops at Camp Wikoff. Of this number about 10,000 are sick. This is the estimate, roughly approximated, as stated by Surgeon-Major Brown. The sick are officially classified under three heads: (1) those who are danger-

ously ill, who are in the general hospital or the detention hospital; (2) convalescents, who are also in the general hospital or who are discharged on furloughs and leave the camp altogether, and (3) walking cases, or "office patients," so to speak, who are not ill enough to go to bed or to the hospital, but who are not well enough for regular duty. Of the seriously sick there are nearly 1100 in the general hospital, and about 600 or 800 in the detention hospital. The very large number of men who are on the daily "office-patient" sick-list seriously handicaps the efficiency of the entire camp. These men are not able to do picket or police duty, or even to serve as orderlies or on special details. In consequence the relatively small number of men who can be called upon for these various duties are overworked, and are unable to attend to their work efficiently. In one battalion of the 24th Infantry only one officer is well enough to perform his duties, and out of the entire battalion only eight well men could be furnished in compliance with an order for a special detail of twenty-four men. How important these various duties are may be readily understood from the statement that they include the policing of the camp and hospital streets, the tents and latrines, the transmission of orders from point to point, the carrying of food and supplies in small quantities, assistance in transferring the newly arriving sick soldiers from the landing to the hospital, manning the ambulances, and a thousand and one other duties. The entire camp is short-handed, and the effect is felt in every department. This is true in spite of the fact that the camp employs more than 2000 laborers, teamsters, carpenters, and various other employees as extra men. It is for the purpose of overcoming this deficiency and of relieving the overworked, many of whom have become ill, that a movement is on foot to add to the camp one or two regiments from other posts which have not been decimated by disease.

Shall Camp Wikoff Be Abandoned?—The question as to the abandonment of Camp Wikoff hinges, of course, as has been abundantly intimated in both the lay and medical press, upon the probable development of typhoid infection of the water-supply. I discussed this aspect of the subject with Dr. Nicholas Senn, Colonel Forwood, and Major Brown. In answer to my inquiry Dr. Senn stated that he had nothing further to add and nothing to withdraw from the opinions which he had already expressed on the subject which have been widely, though not altogether correctly, disseminated through the lay press. He believes that infection of the existing water-supply is absolutely inevitable. How long it will take for this to occur is largely a matter of conjecture. It may take a week, or three weeks; it may exist already, or occur within a day or two. The continuance of existing conditions makes it an absolute certainty sooner or later. In this opinion Colonel Forwood concurred. This infection of the camp with typhoid fever is not in any way a reflection upon the wisdom or skill exhibited in selecting this camp. Typhoid fever, to a greater or less extent is an inevitable accompaniment of all military camps. The United States Army records will show that even two or three companies in garrison for as long as a year, will lose one or two men from typhoid fever. The larger the camp the greater the proportionate number of typhoid cases. Colonel Forwood does not believe that the official water-supply of Camp Wikoff is at present infected, and he further believes that the geologic conformation of the strata met in boring the well used, is such as is most favorable to the preservation of the purity of the water.

Major Brown, when asked as to the possibility of typhoid infection from other sources, such as dust from the roadways, soil pollution on the surface, fly infection from the latrines, etc., stated that every intelligent precaution is being observed to guard against such sources of possible danger. Disinfectants are in use every where throughout the camps, in the latrines, and especially in the hospital wards and streets. Flies are not numerous, a fact which I personally noted. Surface-soil pollution has been provided against by orders, violation of which is met with immediate arrest and imprisonment. A laborer was under arrest at the time of my visit for just such an offense.

I was greatly pleased to learn in this connection from Colonel Forwood that the impression created by the lay press that the regular army medical officers are not in agreement with Dr. Senn in his opinion as to the danger of a typhoid epidemic is absolutely false; on the contrary, he and Dr. Senn are in exact and harmonious accord on this subject.

Hospital Facilities.—There are two hospitals in camp, the general and the detention. The general hospital as it exists to-day is a marvel of perfection, and reflects the highest credit upon the efficiency of Colonel Forwood who planned its arrangement and carried out personally its establishment and equipment. To those unfamiliar with the difficulties and obstacles encountered a full appreciation of the success attained is impossible, but even the most captious can find to-day little if anything to criticise or condemn. Colonel Forwood has been most ably and energetically aided in the entire work by Surgeon-Major Ira C. Brown, in my humble opinion the hardest worked and most patient bearer of many burdens in all Camp Wikoff. I sat in Major Brown's tent for nearly two hours, and during that time by actual count he transacted business with forty-seven different people. A mother wished to find her sick soldier boy; a newspaper reporter wanted a bit of information; a nurse or orderly brought an order to be signed for medicines or delicacies for the sick; a sick furlough was wanted by this one; another wanted a permit to remove one of the dead—so they came one after the other, sometimes several at once. All were treated courteously, every requisition for the sick was granted at once, there was no abruptness or impatience of manner or speech. I found myself wondering again and again how it could possibly be done. Incidentally Major Brown found time in the occasional intervals to give me much information of interest and value. The hospital, he said, was fully equipped with physicians and nurses. One physician, in fact, a volunteer, unable to secure an assignment in the wards, had taken off his coat and done yeoman's service

in the diet-kitchen, rendering most valuable aid to the sick from that position. All hospital supplies, drugs, and appropriate food, and even delicacies for the sick, were on hand in abundance. I, myself, had an opportunity to verify this statement through the requisition clerk of the pharmacy department, who later stated to Colonel Forwood in my presence in presenting a requisition for some twenty or thirty articles the supply of which had been that day mostly exhausted, that he had everything else which was needed, and in abundance.

Major Brown spoke very appreciatively of the work done and the aid rendered by the Red-Cross Society and the Women's National War Relief Association. Not the slightest trace of official jealousy was apparent; on the contrary, his tribute was most generous and frank. Of the sick by far the largest number were cases of malaria; they outnumbered all the other sick, including the "office patients," ten or even twenty to one. The worst and most intractable cases of malaria have been found in the soldiers from Tampa. Many of these cases passed into a typhoid state but were not true cases of enteric fever. True typhoid fever was steadily decreasing both in the number of cases and in the malignancy of the type. The death-rate in the hospital was falling daily. In nearly all cases of both typhoid and malaria the disease germs were present in the system before the soldiers had landed. Much of the fatality from pernicious malarial fever in Cuba and elsewhere has been due to the fact that a great many of the surgeons, especially the volunteers from the New England and Northern States, were not familiar with the heroic treatment necessary. They gave 3 and 5, and sometimes 10, grains of quinin every two or three hours, when they should have given 20 grains at a dose, or even more until the disease was checked. To those who have practised medicine North and South, and who are familiar with the difference between the malaria of the South and the so-called, or it may be actual malaria of the North, this statement possesses a peculiar significance. It also explains the frequency of relapses and the increased virulence of the malarial poison from a prolonged stay and uncontrolled development in the system.

Of the detention hospital, its equipment, efficiency, and management, I can only report at second hand, as I did not visit it at all. I was reliably informed, however, that it is at present as free from all openings for criticism as the general hospital. This was not the case, in one respect at least, a short time ago, since a most serious mistake existed in the appointment as chief diagnostician of a medical man whose qualifications were pitiably deficient. Of this appointee I was told, he had never seen a case of yellow fever in his life. His successor is, I understand, a most capable and efficient medical officer, possessing special qualifications for his post.

The Landing of Soldiers.—Nearly all the troops coming to Camp Wikoff arrive on transports and are landed at one of the two docks, both of which are near the railroad station. It was here that I found most opportunity for criticism, and much, very much to condemn. Thankful indeed should be the returning soldier who passes this Rubicon with safety or even with life. There are two docks, the one owned or controlled by the railroad, near the depot, accessible with some difficulty, the approach being over a network of car-tracks and down a rather steep embankment; the other, perhaps a quarter of a mile distant, much more advantageously located and easy of approach. The latter dock is private property, but its importance and advantages being seen at once by Dr. Kinyoun of the Marine Hospital Service, it was at his suggestion seized and made the headquarters of the Marine Hospital Quarantine Service, which is represented by Drs. Magruder, Kinyoun, and Brunner. These three gentlemen, amply equipped with able assistants, ten in number, and experienced attendants to the number of twenty-four, have charge of all water quarantine. Their equipment is superb and the service has been absolutely without reproach except from one source, which in reality reflects the more credit upon them, a matter to which I shall later refer at more length.

A lookout watches for an expected transport. As soon as the vessel is sighted in the offing Dr. Magruder goes out and boards and inspects her. All passengers to be landed are put through an elaborate routine of disinfection, which process includes, of course, all equipments, clothing, and, indeed, everything which is to be brought on shore. A specially designated medical officer is then notified that the transport is ready to be unloaded, being notified at the same time of the number of sick on board. This medical officer is supposed to remain on duty at the dock and superintend the landing of the sick, providing fresh milk, soup, necessary drugs and stimulants, as well as stretchers and ambulances. An officer from the Quartermaster's Department is also on duty here. These sick men are carried at once to the detention hospital. Not knowing exactly when a transport is to arrive or how many sick are on board, each arrival involves a special order for supplies, ambulances, etc., through various channels, with all the cumbrous details of red-tape routine, involving invariably some delay. Such delay, together with inefficiency in providing for the situation, has cost more than one life, one poor fellow recently dying on the dock for the lack of a stretcher and a little whisky. If the medical officer in charge had had *on* his person for this poor fellow's use one-tenth of the whisky which he had *in* his person one life at least could have been saved.

The sufferings and hardships of *privates* on these transports, as seen by eye-witnesses who told me of them, almost exceed the limits of human belief. Ships have come in, notably the "Mobile" and "Catonia" loaded with desperately sick men piled like baggage in the hot, stifling hold, with only army rations for food and not enough of that, rotten water, no medicines, and not even a surgeon in attendance, while the officers, to their everlasting shame and disgrace be it said, have come in healthy, well-kept, and attended by servants, fed on the best food, including fresh beef and vegetables, and with not only water but in some instances ice. My informant, who mentioned only what he saw, told me that no less than sixteen cases of insanity had been noted by him among the returning soldiers due to suffering and starva-

tion. No sick-records accompanied the men, not even the diagnosis. In many cases the men did not even know their doctors. Men sick with malaria, typhoid, dysentery, and sometimes yellow fever, were all bunched in together and the diagnosis could only be made after some days of observation in the detention hospital. This fact, by the way, explains why it has been impossible to send the typhoid or any other patients directly into the hospitals of New York, Brooklyn, Boston, Philadelphia, and other cities. The diagnosis had to be made in the detention hospital. Many of these men killed themselves through a ravenous indulgence, half starved as they were, in the sandwiches and soups which they greedily ate, helping themselves without knowing the danger and without being guarded from it by careful discrimination and oversight. Many of these unfortunate conditions are attributable to gross carelessness of the officers under whose supervision the transports were unequally loaded in Cuba. Some vessels with a capacity for 350 brought only a few officers and attendants, while others were badly crowded.

It is self-evident, of course, that sick men in such quarters and under such circumstances should be landed as expeditiously as possible. Even an hour's delay might, and often doubtless did, mean the death of a man. A due appreciation of this necessity should have led, one would think, to the observance of every precaution in order to avoid delay, and yet, as a matter of fact, no vessel has been unloaded yet without the loss of several hours of valuable time unnecessarily. I myself was witness to this fact. The "Roumania" was sighted early Sunday morning in the bay. Dr. Magruder went out and boarded her. At 10 o'clock he notified the proper authority that the troops could be landed. It was four o'clock in the afternoon before she was brought to the dock. She had on board 660 soldiers, more than 200 of them sick. A part of the delay was due to slowness in filling the requisition for milk. This was not the fault of the officer in charge, however. Two hours more were lost hunting for the medical officer, who was finally found, I was told, in a privy asleep. It was expected that all the soldiers would be landed by ten o'clock that night. To some of them that ten-hours' delay meant death. In some reliably reported instances—one was mentioned to me specifically by an eye-witness—the landing of several hundred sick and starving men was delayed for hours by the inhumanity of the officers on board in insisting that they be disinfected and allowed to land first. The colonel of the regiment had to exercise his full authority to control a condition of almost open mutiny among his officers. There were, of course, brave, humane, and kindly officers—officers who gladly sacrificed their own comfort for the welfare of their men. They were, in fact, in a great majority, but the brutes were far too numerous for the honor and good name of our Army. It is to be hoped that this particular matter will occupy the closest attention of the proper investigating authorities. If one-tenth of what I was told is true, and I have no reason to doubt one word of it, more than one officer, regular and volunteer, should have his straps torn from his shoulders and his sword broken.

A REFUTATION OF THE FALSE STATEMENTS CONCERNING CAMP WIKOFF.

[From Our Special Correspondent.]

CAMP OF THE ROUGH RIDERS, CAMP WIKOFF, MONTAUK POINT, L. I., September 6, 1898.

HAVING been at Montauk Point for more than two weeks, and having carefully inspected every part of the encampment on my own account, and not having seen any daily papers, I was horrified to read a day or two since that this was indeed a pest-infected camp, and that it was only a question of a few days before we should all be occupying six feet of earth on the Golgotha on the hill near the general hospital.

I started for this sick bay in fear and trembling; its condition must be beyond words, the death-rate appalling! I shuddered as I passed a water-pipe containing the death-dealing fluid told of in the papers, and made a long detour to avoid one of the small ponds laden (as I had read) with malarial germs which were far more deadly than any we had gotten into our systems in that wretched Cuba. I had heard from the mother of a 71st New York boy that he had had nought but coffee and hardtack at Col. Forwood's hospital, so I filled my saddle-bags with extract of beef, jams, and marshmallows. This may seem a curious mixture for a physican to take to the sick, but another mother had brought this combination to the men in our regimental hospital, and complained bitterly that my friend, Dr. Forwood, had not allowed her to distribute them at his place, for, she said, "several poor sick fellows of the 33d had written friends that they were not permitted these and such delicacies." The actual conditions which I found at the general hospital I shall give later in this letter.

To one who is familiar with this encampment the alarming reports which certain papers have sent out are little short of mendacious. Families all over the country are in a panic, and terrible and unnecessary suffering has been caused. Poor people have spent their little savings and been led into debt to pay their way from far distant points to rescue their sons from the death and starvation which they had read was encompassing the boys here. General Wheeler told me of a case of an old couple who had come several thousand miles and brought with them a little bag of things for their starving boy. Their starving boy was, as a matter of fact, making a good recovery in the hospital.

I now propose to give a plain and absolutely just account of matters here. I hope to show how little truth there is in all these wild stories, and incidentally how unjust are the criticisms of Dr. Forwood.

A. The Situation of the Camp.—This was decided (1) after careful consideration of the climate and weather prevalent here at this time of the year, and from this standpoint the decision was a wise one. *It has rained one day in the last twenty.* (2) After a thorough investigation of the geological formation, with reference, of course, to the water-supply. This island lies upon what is known as the Potomac beds, the strata consisting of alternate layers of clay, gravel, and sand, extending down to the rock. It goes without saying that this forms an

ideal combination for a pure water-supply. An examination of the water made *before* the final decision was made showed that it contained neither limestone, sulphur, gypsum, nor salt. The artesian well from which our water is taken was sunk to a depth of from fifty-five to sixty feet; that is to say, the six-inch pipe goes to that depth. A consideration of the strata shows that any infected water which might percolate to that depth must have been cleared of its impurities. The newspapers have had much to say about the small ponds which dot the surface here. These, of course, have a clay bottom through which the rain-water does not percolate. It is practically all evaporated. The water here is the same used all over Long Island, and I have never heard that it is poisonous hereabouts. The impression has been given by some papers that we are drinking the water of the lake on the right near the station. One correspondent sent by a certain "public irritator" gravely stated that he saw men washing their clothes and watering their horses in the fount of our water-supply; and this grossly ignorant statement I have heard quoted time and time again.

The ground here becomes dry surprisingly quick after a rain; there is always a cooling breeze, and a physician who has practised in this immediate section for twenty years tells me there is very little if any malaria here, and finally, what the New York *World* is pleased to call the swamps "about which our brave soldiers are encamped" are, as I have shown, absolutely harmless little surface pools. So much for the situation of this much-abused camp. General Wheeler told me, and gave me permission to say so, that he had never seen nor could he think of a more ideal situation for a camp.

B. The General Hospital, the Death-rate, and the Care Received by the Sick.—There has been at times a lack of cots, *but no patient has ever slept on the bare floor*. Mattrasses there have always been in plenty. I have seen the hospital when it contained no less than 1600 sick; at such a time there has been here and there a commode which should have been emptied; there have been men dying without a woman's hand to soothe (women's hands are always supposed to soothe), but who were unconscious and beyond any human power to help. I have heard men complaining that they were not immediately waited upon, which is not to be expected in such a huge place, *but* I have never seen any one really neglected. I have seen distracted parents and friends bitterly complaining that they could not find some sick man. For this Dr. Forwood and Dr. Brown have been abominably abused. The parents and friends did not know that many men have been brought to Dr. Forwood and to Dr. Brown either totally or partially unconscious and without even a piece of paper to establish their identity. In this connection I am convinced that at first there was a sad lack of method and care in keeping the records. But this has been remedied.

As to the death-rate. This has been grossly and shamefully exaggerated. Up to 3 P.M. Sunday, September 3d, 6040 cases had been received. There had been up to the same hour 150 deaths; making a death-rate of exactly two and one-half per cent. Surely this should satisfy even the most fault-finding; it is very small in any case, but incredibly small when the condition of the men when received is considered, and bears a striking tribute to the care received in the hospital.

As far as the condition of the sick men in the regiments goes, their state could be and is being improved. Division hospitals are now established (they should have been erected before) and the men of the different divisions will soon be as well cared for as the sick in the big hospital.

This brings me to the question of regimental hospitals; and whatever may be the objection to them in the field *they should be a part of the medical service of every regiment when encamped for any length of time*. With the permission of Colonel Roosevelt I established one for our regiment, and I do not hesitate to say that it has been nothing short of a blessing to the sick, and we have seen a number of men really restored to health through the care and nursing here received. Our treatment has consisted largely if not entirely in careful dieting. The Cuban experience left many with stomachs and intestinal canals in a frightful state. The general health of this regiment is more than satisfactory, and indeed, that of all the troops quartered here is surprisingly good.

And so I have given you the facts about things here. I trust what I have written will serve to stop, in part at least, the panic about the "suffering and starvation of our poor troops," about which the papers have so much to say. I might add that I had a long interview on this whole matter with Dr. Forwood, and was also most cordially received and given a long talk by that most courteous of old soldiers, General Wheeler.

FRANK DONALDSON, M.D.,
Assistant-Surgeon, U. S. V.

GENERAL STERNBERG'S ANSWER TO HIS CRITICS.

To the Editor of the MEDICAL NEWS.

MY DEAR SIR: I am very much occupied with important official business in connection with the care of our sick soldiers in all parts of the country, but will take a little time to give you my opinion with reference to Montauk Point.

I am responsible for the selection of Montauk Point as a camp for our returning soldiers, and I do not believe that another place could have been found on the Atlantic Coast presenting so many advantages. We have over five thousand acres of land, never before occupied by camps or by human habitations. The soil is covered by a good growth of grass and affords excellent camping-ground. We get good water from wells, which are sufficiently removed from the camps to prevent any possibility of fecal contamination. The Point is swept by the ocean breezes and has all the advantages of a seaside resort. There is a fine sheltered harbor where our largest ships can anchor, and there is a line of railroad giving direct communication with Brooklyn and New York. No doubt this camp, if occupied for some time without proper regard to essential

sanitary precautions, would become infected with typhoid fever as other camps have been.

If the recommendations, which I made in my Circular Letter of Instructions, April 25, 1898, had been followed at Camp Thomas, Camp Alger, and other camps where typhoid fever has prevailed, I believe that the number of cases of this disease would have been comparatively small. I believe, with other sanitarians, that typhoid fever is a preventable disease, and long since in my prize essay on "Disinfection and Individual Prophylaxis against Infectious Diseases," published in 1886, I insisted upon the disinfection of the excreta of patients with typhoid fever in the following words:

"The dejections of patients suffering from an infectious disease should be disinfected before they are thrown into a water-closet or privy vault. This is especially important in cholera, typhoid fever, yellow fever, and other diseases in which there is evidence that the infectious agent is capable of self-multiplication, in suitable pabulum, external to the human body."

In my "Manual of Bacteriology" this recommendation is repeated, and detailed instructions are given with reference to the disinfection of excreta. I also call attention to the value of quicklime as a disinfectant, as follows:

"Experiments made in Koch's laboratory in 1887 by Liborius led him to place a high value upon recently burned quicklime as a disinfectant. More recent experiments by Jäger, Kitasato, Pfuhl, and others have shown that this agent has considerable germicidal power in the absence of spores, and that the value which has long been placed upon it for the treatment of excrementitious material in latrines, etc., and as a wash for exposed surfaces, is justified by the results of exact experiments made upon known pathogenic bacteria. The germicidal power of lime is not interfered with by the presence of albuminous material, but is neutralized by phosphates, carbonates, and other bases, and by carbonic acid.

"In the writer's experiments a saturated aqueous solution of calcium oxid failed to kill typhoid bacilli; but when suspended in water in the proportion of 1:40 by weight this bacillus was killed at the end of two hours. Anthrax spores were not killed in the same time by a lime wash containing twenty per cent. by weight of pure calcium oxid. According to Kitasato, the typhoid bacillus and the cholera spirillum in bouillon cultures are destroyed by the addition of one-tenth per cent. of calcium oxid. Pfuhl experimented upon sterilized feces to which pure cultures of the typhoid bacillus or cholera spirillum were added. The liquid discharges of patients with typhoid fever or diarrhea were used for the purpose. He found that sterilization was effected at the end of two hours by adding fragments of calcium hydrate in the proportion of six per cent., and that three per cent. was effective in six hours. When a milk of lime was used which could be thoroughly mixed with the dejecta the result was still more favorable. A standard preparation of milk of lime containing twenty per cent. of calcium hydrate killed the typhoid bacillus and the cholera spirillum in one hour when added to liquid feces in the proportion of two per cent.

"The experiments with this agent show that time is an important factor and that much longer exposures, as well as stronger solutions, are required to destroy pathogenic bacteria than is the case with chlorid of lime. For this reason we still give the last-named agent the preference for the disinfection of excreta in the sick room. But in latrines the time required to accomplish disinfection is of less importance, and *we are disposed to give recently burned quicklime the first place for the disinfection of excreta in privy vaults or on the surface of the ground.* It may be applied in the form of milk of lime, prepared by adding gradually eight parts, by weight, of water to one part of calcium hydrate. This must be freshly prepared, or protected from the air to prevent the formation of the inactive carbonate of lime."

In the "Manual for the Medical Department," which is supplied to every medical officer in the service, I have introduced the following paragraphs:

"121. Sulphate of iron and other cheap antiseptics and deodorants may be used when necessary. But the necessity for their use is a reproach upon the sanitary police of a post, and should only be required under exceptional circumstances. The alvine discharges of healthy persons do not require disinfection, and when properly disposed of do not require treatment with any chemical agent whatever. If water-closets or earth-closets are offensive, this is due to faulty construction, to insufficient supply of water or dry earth, or to neglect of ordinary cleanliness. The attempt to remedy such defects by the systematic use of antiseptics is expensive and unsatisfactory in its results. The same is true of foul drains, bad-smelling urinals, accumulations of garbage, etc. The proper remedy for such conditions is cleanliness and strict sanitary police.

"122. When accumulations of organic material undergoing decomposition cannot be removed or buried they may be treated with an antiseptic solution, or with freshly burned quicklime. Quicklime is also a valuable disinfectant, and may be substituted for the more expensive chlorid of lime for disinfection of typhoid and cholera excreta, etc. For this purpose freshly prepared *milk of lime* should be used, containing about one part, by weight, of hydrate of lime to eight of water.

"123. During the prevalence of an epidemic, or when there is reason to believe that infectious material has been introduced from any source, latrines and cesspools may be treated with milk of lime, in the proportion of five parts to one hundred parts of the contents of the vault, and the daily addition of ten parts for one hundred parts of daily increment of feces."

Having thus pointed out what should be done, and having authorized the purchase of quicklime for disinfecting purposes in unlimited quantities at Montauk Point and at our other camps, I am not responsible if there has been a neglect to carry out those sanitary measures which are essential for the preservation of the health of troops in camp. All experienced officers of the line, and medical officers, know that it is dangerous to remain for a long time on one camping-ground. In Circular No. 5 from my office, dated August 8, 1898, I say:

"The attention of medical officers is invited to Circular No. 1 from this office, dated Washington, April 25, 1898.

"The extensive prevalence of typhoid fever in camps of instruction indicates that the sanitary recommendations made in this circular have not been carried out. If medical officers have failed to make the proper recommendations as indicated, the responsibility rests with them. If the recommendations have been made and not acted upon by those having authority in the various camps, the responsibility is not with the Medical Department, but these recommendations should be repeated and commanding officers urged to move their camps at frequent intervals and to maintain a strict sanitary police."

At Montauk Point there is plenty of room and there will be no excuse if the camps are occupied for so long a time as to endanger the health of the troops through typhoid infection. Moreover, the regiments now there are some of them being mustered out and others have been ordered to return to the military posts occupied by them before the war. We are doing our best to take care of our sick, and, at the same time, to prevent the extension of infectious diseases at Montauk; and, as I have already stated, I consider this an ideal place for the purpose.

Very truly yours,

GEO. M. STERNBERG,
Surgeon-General U. S. Army.

WAR DEPARTMENT,
SURGEON-GENERAL'S OFFICE,
WASHINGTON, D. C., September 4, 1898.

BLOOD EXAMINATIONS AT CAMP WIKOFF.

BY J. RICHARD TAYLOR, M.D.,
OF SAG HARBOR, N. Y.

HAVING heard many conflicting accounts of diseases to be found at Camp Wikoff I spent almost a week at the general hospital there recently by invitation of Colonel Forwood, Assistant Surgeon-General United States Army, and made microscopical examinations of the blood of such patients as were placed under my care for that purpose. All who were examined had been thoroughly exposed to malaria and most of them had received more or less quinin. The examinations were all made with fresh blood and from 3 P.M. Tuesday until 6 P.M. Saturday forty-three were examined for malaria and one for tuberculosis. The following list shows twenty-four cases in which the plasmodium was found in repeated examinations and nineteen cases in which the results were negative so far as the microscope was used, though in most of these the clinical evidence was plain and correct.

Tuesday, August 23, 1898. Lieutenants T. and A. M. M., spherical hyaline bodies, non-pigmented, extracorpuscular; Captain H. and Lieutenant L., spherical hyaline bodies, non-pigmented, extracorpuscular, also a few ring-shaped bodies free.

Wednesday, August 24th. Captain S., intracorpuscular, non-pigmented bodies; Lieutenants R. and W., large pigmented spherical bodies, extracorpuscular; Lieutenants La F. and H., examination negative; Lieutenant J. K. M., intracorpuscular non-pigmented bodies; Private H. G., Co. C, 8th Regulars, free pigmented spheres.

August 25th. Lieutenant L. G. B., 2d Mass., examination negative; Lieutenant P. W. D., 22d U. S. Infantry, intracorpuscular hyaline bodies with unmistakable evidence of typhoid fever; Lieutenant H. C., 22d U. S. Infantry, examination negative; Lieutenant E. J. L., intracorpuscular non-pigmented bodies; Lieutenant H. T. G., 2d Mass., intracorpuscular non-pigmented bodies; Captain J. J. L., 2d Mass., intracorpuscular non-pigmented bodies; Lieutenant F. B. M., 2d Mass., intracorpuscular non-pigmented bodies; Captain J. J. C., 22d U. S. Infantry, intracorpuscular non-pigmented bodies; Lieutenant H. L. J., 22d U. S. Infantry, intracorpuscular non-pigmented bodies; Lieutenant A. C. K., 2d Mass., intracorpuscular non-pigmented bodies, clinical evidence of typhoid fever; Lieutenant F. W. S., 12th Regulars, examination negative; Lieutenant W. L. T., 22d U. S. Infantry, intracorpuscular non-pigmented bodies; Lieutenant W. B. L., 9th Infantry, examination negative; Captain J. F. R. L., 6th Cavalry, examination negative.

Friday, August 26th. Dr. J. S. K., Assistant Surgeon Division Hospital, examination negative; Captain C. H., 4th U. S. Infantry, free pigmented crescents in *large* numbers, semicomatose—a pernicious case; Lieutenant A. M. H., 4th Artillery, free pigmented crescents, not very plentiful, general condition good; Lieutenant J. A. M., 24th U. S. Infantry, examination negative; Lieutenant H. R. P., 17th U. S. Infantry, examination negative; Lieutenant W. M. B., 8th Ohio, small pigmented bodies, extracorpuscular, very active; Lieutenant A. I. R., 71st N. Y., small non-pigmented bodies, extracorpuscular, very active.

Saturday, August 27th. Lieutenant H. E. B., 8th Ohio, examination negative; Lieutenant H. A. L., 7th U. S. Infantry, examination negative, wounded at El Caney, photo. in *Munsey's*, page 811, September, 1898; Lieutenant J. C. R., 6th Cavalry, examination negative, delirious, had received no quinin; Lieutenant A. C., 17th U. S. Infantry, examination negative; Private A. D. K., Co. H, 2d Mass., examination negative, patient comatose; Lieutenant B. F. H., 17th U. S. Infantry, examination negative; Lieutenant K. W. T., 8th Ohio, examination negative; Lieutenant H. M. B., 1st D. C. Volunteers, examination negative; Lieutenant R. B. H., 1st D. C. Volunteers, examination negative; Major C. H., 1st D. C. Volunteers, free pigmented crescents; Lieutenant P. W. D., 22d U. S. Infantry, intracorpuscular non-pigmented bodies, still undoubted evidence of typhoid fever; Sergeant T., Troop E., Rough Riders, clinical evidence of tuberculous infection proved by finding the tubercle bacilli in sputum.

Most of the above subjects were very much troubled with nausea and diarrhea, a condition *quite common* in cases of tertian fever on Long Island. Quinin given improperly only aggravates the distress of the patient in such cases, while in small doses properly combined with other remedies it is retained, absorbed by the system, and promptly relieves all the above conditions. Unfortunately the pharmacy at headquarters was not stocked with necessary remedies and the patients had to swallow or reject such doses as could be found. The surgeons were

obliged to hear constantly, "the goods are not in stock and prescription cannot be filled." Comment is unnecessary and the words one wishes to utter are not sufficiently expressive.

CLINICAL MEMORANDA.

MALARIA MANIFESTED BY EPILEPTIFORM CONVULSIONS.

By J. B. MAXWELL, M.D.,
OF MT. CARMEL, ILL.

CASE I.—On September 1, 1894, I was called to see Mr. C., married, twenty-three years old, of slender build, on account of his having fits. He, with his wife and others, had come down the Wabash River in an open boat, the journey occupying two or three weeks. He had landed near Mt. Carmel and had been working and fishing, meanwhile living in a tent on the river bank. He suddenly became ill, developed high fever, and in an hour or two had convulsions. I was sent for in the evening, but was unable to see him until the following morning. He had not had a chill, as far as the attendants knew, but had very high fever and one convulsion right after another, there having been sixteen in all. Before I arrived he had become somewhat better, the fever having declined, and the attendants had noticed that as long as he lay perfectly still, the fits did not occur, but when he sat or stood up he was immediately convulsed.

The people were not particularly intelligent, and I did not know just how much dependence to put on what they told me, so I had him stand up, and he had a typical epileptiform convulsion. I had never seen a similar case, but the cachectic appearance, the season of the year, the location of the man's living apartments, the high fever, and things in general convinced me that the trouble was malarial, and I began a vigorous antimalarial treatment, which resulted in complete recovery, there being no recurrence for three months, at which time I lost sight of my patient.

CASE II.—On August 21, 1895, I was called to see George J., single, twenty years old. I was told that he had been having chills and all treatment had been unavailing. He had no appetite, had become very weak, and was having fits often, especially when he tried to walk. My informant gave it as his opinion that the convulsions were due to masturbation. Upon examination I found the patient's liver much enlarged and very tender on pressure. The spleen was enormously enlarged and there was a typical malarial cachexia present. He had been living for some months in the Wabash River bottoms, where ponds are numerous and the conditions for malaria are first-class. I had him stand up, and verified the report of the convulsions that had been given me. I gave him 15 grains each of calomel and bicarbonate of soda, and after the bowels had been thoroughly evacuated I gave him 30 grains of quinin in four doses, two hours apart. I then prescribed a teaspoonful thrice daily of a combination containing 1 dram of sulphate of quinin, 3 drams of dilute nitric acid, and 4 ounces of whisky. His recovery was prompt and perfect. I have seen him occasionally since, and he is well and has had no return of the convulsions.

Only two cases that are at all similar to these have hitherto been reported, so far as I know, the first by Dr. Frederick Hill Stanbro, in vol. 61, page 683 of the MEDICAL NEWS. In this case there was some doubt about the cause of the convulsions, but since they disappeared promptly after the administration of quinin they were undoubtedly of malarial origin. The second case was reported by Dr. E. W. Tudlow, in vol. 67, page 428 of the MEDICAL NEWS. In this case the convulsions were at first somewhat irregular, but later occurred every other day and continued to do so for six months or more, the patient finally being cured by the administration of quinin.

A BROWNIE BABY.[1]

By WHYTE GLENDOWER OWEN, M.D.,
OF WHITE CASTLE, LA.

THOUGH the history of monstrosities is usually relegated to the domain of scientific curiosities, yet the clinical phenomena attendant upon their birth merit the consideration of the obstetrician. And again, when the much-discussed question of maternal impressions can be clearly demonstrated in their production, the subject is one not destitute of interest to all concerned in the evolution of the human race. Allow me, therefore, to claim your attention for a brief description of the following case of labor resulting in a remarkably abnormal development of conception:

On the 25th of last October I was called to see Mrs. B., a multipara, aged twenty-eight years, white, of good personal and family history. She stated that she had been having severe pains about four hours, and an examination revealed an enormous distention of the abdomen, which on palpation showed fluctuation only. The cervix was found to be well dilated, but occupied by the tense bag of waters alone. No fetus whatever could be detected. The same condition of affairs continued a couple of hours, during which time pains of moderate intensity recurred every ten or fifteen minutes. At the expiration of this time I ruptured the membranes, which resulted in the release of a miniature Niagara which fairly deluged both the patient and the bed.

Having "cleared the decks for action" by having the patient dried, regowned, and removed to another bed, an examination was instituted, and instead of the finger impinging upon some known portion of the child's anatomy the os was found to be occupied by a smooth, soft, cartilaginous body. My first impression was that this was a fibroid tumor, and deeming an exact diagnosis imperative for the patient's welfare I administered chloroform and introduced my hand. Imagine my surprise to find that the tumor extended to and connected with the head of the fetus.

A dose of ergot, and friction applied to the fundus uteri, excited vigorous contractions, which soon resulted in the delivery of the child, and cleared up the mys-

[1] Read at the Annual Meeting of the Louisiana State Medical Society, New Orleans, May, 1898.

tery of the presentation. The child was an exact reproduction of one of Palmer Cox's "Brownies," with the grotesque features, frog-like abdomen, and spindling limbs so familiar to all. Its most remarkable feature, however, was its cap—the thing which had puzzled me so greatly in making a diagnosis of the presentation. This consisted of a hood of fibrous tissue, of purplish hue, which originated in a space of probably 2½ inches on the top of the cranium and extended upward and outward about the same distance. The child weighed about eight pounds, was still-born, and it was soon the center of attraction for a curious throng of feminine neighbors who flocked in to view it.

Reverting to the cause of this *lusas naturæ*, I ascertained that during the first month of the mother's pregnancy her little boy brought home a wooden "Brownie" about 15 inches long, with its cap painted red. He threw this unexpectedly into his mother's lap, thereby giving her quite a shock, though afterward she was considerably amused upon examining the toy. I was extremely anxious to obtain possession of the child in order to submit it for your inspection, but as this conflicted with the religious convictions of the parents I was unable to do so.

MEDICAL PROGRESS.

Pneumonia after Ether. — ANDERS (*University Med. Mag.*, August, 1898), in an exhaustive article upon ether pneumonia, says that he has collected statistics of 12,842 etherizations, thirty of which were followed by pneumonia. The percentage of pneumonia is, therefore, .23; while if only gynecologic cases are included, the percentage is as high as .33.

Regarding the cause of such pneumonia, the writer says that the old idea that it is due to careless exposure to cold, etc., will not explain all cases. He further states that the theory that infection takes place from the mask or cone used, is not supported by facts. Thus, in hospitals, where a fresh sterilized towel was employed, the percentage of pneumonias was not less than that where a fixed apparatus was employed. Besides this, the apparatus with which nitrous oxid is given, is of all others the best adapted for the conveyance of infection; yet no case of pneumonia following the administration of this anesthetic is on record.

Others have stated that mucus from the nose and throat, being drawn into the trachea during narcosis, predisposes the patient to an attack of pneumonia. This may be avoided in large measure by keeping the head of the patient low. The writer is inclined to attribute some weight to this cause, as eight of the thirty patients who developed pneumonia admitted having had a previous cold or cough. Sex and age seemed to have no etiologic importance, and none of the patients, as far as could be ascertained, had had a previous attack of pneumonia. The greater likelihood that a gynecologic operation will be followed by pneumonia, is due apparently, to the greater length of such operations.

Regarding the clinical peculiarities of ether pneumonia, Anders says: "The clinical features bear a striking similarity to those of secondary pneumonia, as do also the morbid lesions, according to the distribution of the areas implicated, and as evidenced by the physical signs. It has been frequently observed that there is a tendency in secondary pneumonia to commingling with small areas of bronchopneumonia. Moreover, the lung tissue surrounding the hepatized areas is apt to be more extensively congested than in the primary form. Microscopically, the combined presence of the streptococcus and the micrococcus lanceolatus have been noted. From the latter fact, coupled with the well-established clinical similarity between secondary and ether pneumonia, as observed by myself, I do not doubt that a mixed infection often occurs in the latter form of the disease."

The diagnosis is easily made if the chest is examined. Unfortunately, this is often not done immediately, the symptoms being attributed to the wound. It is, therefore, desirable to emphasize the important fact that the sudden accession of fever, particularly if it occur coincidently with thoracic pain, however slight, following an operation, renders a physical examination of the thorax imperative.

Of the mortality in the thirty cases, the author says: "As stated, thirteen of the thirty cases of pneumonia proved fatal, a percentage of 43.3. Surely, if ether be responsible for these fatalities, even though indirectly, there is great likelihood that, when other ill consequences are considered, it is but little less dangerous to life than its rival, chloroform."

The treatment of the patient before an operation which is most likely to lessen the danger of subsequent pneumonia includes the cure or amelioration of any existing bronchitis or rhinitis. At all events, a thorough cleansing of the mucosa of the nasopharynx is imperative, so as to prevent the aspiration of irritating morbid products (desiccated secretion, incrustations), with their lurking micro-organisms, from the higher to the lower respiratory passages, and the setting up of pneumonia, since ether promotes separation of these foreign substances. An appropriate toilet of the nasal passages as a routine practice is to be advised and encouraged. To this should be added a mouth-wash of some efficient antiseptic solution, and a similar spray for the throat. The head of the patient should be turned to one side from time to time during the operation to allow the escape through the mouth and nostrils of the mucus which collects in the pharynx. And most important of all, the time of anesthesia should be shortened as much as possible, consistent with the thorough execution of the operative procedures. In long operations especially, the cooling of the skin of the patient should be guarded against, and no sudden transition from a hot operating-room to a cold ward or hall should be allowed. It goes without saying that the quantity of ether used, and the mode of its administration, are important factors in the development of ether pneumonia.

Acute Chloral Dementia Simulating Paretic Dementia.—COE (*Medicine*, August, 1898) emphasizes the wisdom of keeping a patient to whom hypnotics have been given under

observation a sufficient length of time to learn if perchance it may not be a case of drug-habit insanity, as even learned alienists may be mistaken in the diagnosis of these cases. Two patients were recently brought to him for treatment, in whom the symptoms of paretic dementia were so well-marked that this diagnosis had been made without hesitation. One of these was a lady, aged fifty-six, married, of good family and without hereditary taint, who had been ill during the past five years, and had delusions, transitory in character, of a grandiose form, some months previous to the time of coming under the observation of a most excellent family physician. Ataxia was marked, especially in the lower limbs. General tremor was present, and the tongue could scarcely be extended, so marked was the trembling of that organ. There was pupilary inequality and the speech was tremulous. Insomnia was marked, and for this and the shifting pains in the back and limbs a well-known proprietary article, the chief constituent of which is hydrate of chloral, had been employed in moderate quantities for about a year and a half. Recently this amount had been increased, yet the total amount taken did not exceed on an average twenty grains of chloral daily. The prognosis which had been given was gloomy; but in six weeks after the discontinuance of all hypnotics, the patient was so far restored to health, that she assumed the management of her estate.

In the other case, the symptoms were similar, except that the mental break down was more complete, and the patient by his own admission, had taken large doses of chloral. The withdrawal of this drug was followed by the most distressing symptoms, but in four weeks they all subsided, and the patient was able to take an ocean journey to his own home.

THERAPEUTIC NOTES.

How to Rub in Salicylic Acid in Rheumatism.—HUSSON (*Rev. de Therap.*, July 15, 1898) employs the following formula when he wishes to introduce salicylic acid through the skin of a patient who is suffering from rheumatism:

℞	Ac. salicylic. pulv.	3 j
	Ol. terebinth.	3 j
	Lanolin	3 viij.

The skin is first to be cleansed with soap and water, but is not to be shaved, as the pulling upon the little hairs favors the introduction of the remedy through the skin. Friction should last for at least five minutes. After the friction is over the limb should be wrapped in cotton in order to preserve an even temperature. Treatment is to be repeated daily. One inconvenience of this method of administering salicylic acid is the desquamation of the epidermis, on account of the solvent action of the acid upon the cornified layer. However, this desquamation does not occur until five or six days have passed, and by that time the therapeutic effect of the drug has usually been fully realized. At any rate, desquamation is not painful, and treatment should not be suspended for this cause. This method of administering salicylic acid is rapidly gaining favor on account of the annoying gastric complications which so often follow the ingestion of the drug or its compounds.

Atropin in Delirium Tremens. — TOUVIME (*Rev. de Therap.*, July 15, 1898), acting on the statement of Mendel that in delirium tremens some of the centers of the brain are in a state of depression, has attempted to remove this depression and so favor the recovery of the patient by the administration of caffein and atropin subcutaneously. The results obtained with the former drug were found to have only a theoretical importance, but with the latter the beneficial effects were prompt and striking. He administered it to 11 patients, of whom 6 had furious delirium, and 5 delirium of a mild type. Of these 11 patients, 10 became calm after a single injection of atropin, and in fifteen or twenty minutes they were all asleep. The dose employed was 1/60 of a grain of the sulphate. In the eleventh case, 1/40 of a grain was given in the evening to the patient, but he still remained greatly agitated. On the following morning, after a cold bath, he became more quiet, and toward evening, he, too, fell into a refreshing sleep. A non-alcoholic patient who suffered from post-operative delirium, received injections of 1/40 of a grain of the sulphate each morning and evening. He was completely restored in five days. These most interesting facts certainly call for a further trial of this drug in such cases.

Results of the Immunization of Fifty Children.—COUES (*Boston Med. and Surg. Jour.*, July 14, 1898) gives an account of the effects of the immunization of the children in St. Mary's Infant Asylum, Boston. An epidemic of diphtheria of unknown origin had broken out among them, and from February 15 to March 22, 1898, eighteen cases of the disease occurred. On the latter date it was decided to immunize all the children then in the asylum, and also all those who might be admitted. This plan was forthwith carried out, and for nearly three weeks from that date no cases of diphtheria occurred. At the end of this period, and before any children were immunized for a second time, cases of diphtheria again began to occur. They continued to develop until all the children were again immunized, and then, as at first, no fresh cases of diphtheria developed.

The immunizing dose varied from ½ to 5 centimeters of a serum of 1000 units strength. Urticaria occurred in fourteen out of the fifty children who were given injections. The older children were not affected at all by the injections, playing about as usual. The infants cried, and were restless for a few hours, and their temperature sometimes reached 101° F.

An Agreeable Form of Administering Trional.—According to DR. HABERMANN'S observations (*Allgm. Med. Central Zeitung*, No. 32, 1898), the exhibition of trional in a carbonated alkaline water facilitates its absorption, renders it more agreeable to take, and produces hypnotic effects in much smaller doses.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

PROPER FOOD THE ESSENTIAL FOR OUR RETURNING SOLDIERS.

FROM week to week it has been the unpleasant duty of the MEDICAL NEWS to protest loudly against the unnecessary waste of life that followed the assault upon Santiago, attended the transports while returning with the sick and wounded, and, finally, is disorganizing and necessitating the abandonment of the volunteer camps. The apparent inability of the soldiers to recover their strength and get upon their feet suggests something more than official incompetency, and makes the demand for Congressional investigation imperative. The assertion of Commissary-General Eagan that the army ration is regulated by an act of Congress, that it is prescribed by a hard and fast law of the land which neither he nor any other officer has a right to change, throws a flood of light upon the slowness with which the troops, as a whole, are recovering their wonted physique and why patients afflicted with dysentery and diarrheal troubles so generally succumb.

In the army two classes of men are recognized and provided for: sick men and well men. The sick men are in hospital, the well men outside. The men not in hospital are supposed to be able to attend to their duties—no matter what their condition there are no special foods for them. Hardtack and bacon constitute the prescribed fare. They must eat that or nothing. This arbitrary classification has worked disastrously at Camp Wikoff and is continuing to do so. The men there who have stomachs for regular army rations are a very inconsiderable minority. The surgeons in testifying to the cause of death are compelled in many instances to write "starvation" owing to the absence of any pronounced disease. The general vitality is so impaired that the digestive functions are not equal to the mastery of regular army food. The whole camp should have been declared by the surgeon-in-chief "a hospital camp," and every soldier, upon his arrival, put upon hospital diet, with the privilege of supplementing it if he had the inclination and capacity for a hardier menu. Many convalescents could thus have been saved from a relapse and death, and many "ailing" men could have been kept out of hospital. The good condition of the Rough Riders is largely attributed to the delicacies which a diet-kitchen established in their camp has been providing for those unable to eat ordinary food.

The Porto-Rican army, which is already seriously infected with malaria, typhoid fever, and intestinal disease, is on its way home. May it not be that the experience gained at Camp Wikoff will lead to the prompt establishment of diet-kitchens throughout their detention camp so that every soldier can have all the nourishing soups, eggs, custards, broths, and other special foods that he may need? Let us grant that the established army ration is the best diet for the soldier in active service; but army traditions, and army customs, and army regulations should not carry us so far as to forget that the volunteer of three-months' training and experience has not become so inured to hardtack and bacon that his vital powers cannot be better sustained and the advance of disease better resisted by a more easily assimilated diet. Being a soldier no longer means that he must get his nourishment out of hardtack and bacon, or die.

TROPICAL DIARRHEA.

AMONG our troops in the tropics, equally in the West and East Indies, there will be more or less mortality due to the prevalence of both tropical

diarrhea and tropical dysentery. These two diseases as met with in the tropics are much more grave in results and less amenable to treatment than in the temperate zones. They are due primarily to climatic influences which cause debility and cachexia. Tropical diarrhea is most frequently found among adults. It is essentially a chronic disease, insidious in onset, slow in progress, and if allowed to run its course unchecked, produces permanent pathologic changes in the digestive tract. Its etiology is found in anything that upsets the nervous equilibrium—anxiety, sleeplessness, errors in diet, overfeeding, excessive use of stimulants, chronic malarial infection and impure water-supply. Interference with the portal circulation, especially in cirrhosis of the liver, found among the high-livers of the foreign colonies in China, India, and the Straits Settlement, who, in addition to eating highly seasoned food at late hours, begin the day with cocktails, drink half-and-half frequently during its course, and go to bed on a nightcap of Scotch whisky. The preparation of the system having thus gone on insidiously, a sudden change of temperature, causing chilling of the abdomen, sudden meteorologic changes, without any appreciable surface chilling, or the shock from an imprudent cold plunge, will be immediately followed by the prodromal symptoms of the disease, which generally are slight, being only looseness of the bowels attended by tormina, quick in onset, urgent in character, and which are relieved by the passage. Some cases may have a history of the existence of a chronic non-inflammatory diarrhea a few days or weeks preceding these more acute symptoms. The character of the dejecta varies, but generally at first they are bilious, becoming lighter in color and frothy. In a few instances the first few days of the disease will be marked by feces perfectly natural in appearance but ejected with great precipitancy and some pain a number of times a day.

This condition of affairs may continue a few days or weeks, the patient growing gradually more emaciated, anemic and weak, yet, strange to say, possessing an excellent appetite and eating not only regularly but voraciously. Tenderness of the tongue and aphthous ulcers in the mouth now appear. The patient looks sick, his skin hangs loosely and is of a dirty white hue, and waxy, the fat disappears, the eye becomes glistening and sunken, mucous membranes become pale, the ilia are prominent, the abdomen flaccid and sunken, and by palpation the coils of intestines may be easily marked out. The tongue is now no longer flabby but narrow and red, and its papillæ are imperceptible. The dejecta have become more frequent and fluid, the tormina more severe, and blood may be passed. The heart action grows feeble, mental apathy and physical lassitude are marked, and unless the patient be at once sent north, he soon passes into a hopeless condition.

As tropical diarrhea is the result of a general systemic degeneration, of which the intestinal changes are the most marked, the prognosis must naturally depend upon the stage in which the disease is recognized and treatment inaugurated. If taken in hand before prominent visceral changes have occurred, and if the patient is not debilitated by age or past dissipation, the vast majority of cases should terminate favorably. Perhaps there is no disease in which a greater variety and number of remedies have been recommended by authors of experience. A moment's reflection will convince one that the treatment must be symptomatic; that the symptoms must be traced to their etiology. For example, if there be obstruction to the portal circulation, astringents are contraindicated and catharsis necessary; if the diarrhea be due to cardiac insufficiently producing stasis, digitalis and iron are of great value. Waring, Luinaens, Fothergill, and many others, advocate the administration of ipecac; this may be given in small, frequently repeated doses, or in single doses sufficient to cause emesis. The writer has not been led by experience in either the tropics of the east or west to place much reliance upon this treatment. Most authorities agree upon the value of castor oil repeated according to symptoms and followed by either astringents or antiseptics.

If a single-routine plan were to be adopted for the *majority* of cases, such as are met with in camp where there is no time to go exhaustively into the etiology of each case, it might advantageously be as follows: Calomel in repeated doses for twenty-four doses, to be followed by a full dose of castor oil, and this, in turn, to be followed by a powder of salol, soda, and bismuth every two hours until the patient is convalescent. In the majority of cases, 10 grains of salol alone can be advantageously administered every hour during the first day, every two hours dur-

ing the second day, and, if the case has been a primary one, three times a day thereafter for about one week. If the case be of a more obstinate type, the treatment by salol may have to be continued even two weeks, interrupted occasionally by a dose of castor oil. During this time the diet must be restricted to boiled or malted milk. After the recovery of the patient from the primary attack, recurrences should be avoided by strict attention to prophylactic measures. Abdominal flannel bands should be worn constantly, and the use of fatty, sweet or highly seasoned foods, and alcohol in any form should be forbidden. From long observation among civilians and officers I am able to state unreservedly that even the moderate use of stimulants in the tropics is injurious and liable to cause gastric and hepatic changes which open the way for the gravest form of intestinal complications. Drinking water should always be boiled and filtered, and the receiving-tanks should be regularly inspected by medical officers, and periodically flushed. Exposure to the falling night dew should be avoided, and one should never sit down in wet clothing. In the jungles of Central America and in the lowlands of Central China I have never seen a case of disease due to the patient being wet while in motion or on the march, and often I have known officers and men to be soaked to the skin all day long. The danger lies in not removing the wet clothing when exercise ceases.

Add to these few and simple precautions the immediate dose of an aperient at the slightest sign of intestinal irritation, and a day or two of restricted diet, and the danger of an attack of tropical diarrhea will be greatly reduced.

The treatment of the more severe acute cases and all of the chronic forms can be summed up in a few words: send the patients home, at least temporarily, and on the road treat them symptomatically, always remembering that it is never wise to wait for a temporary improvement in the patient before starting him on the journey.

J. EDWARD STUBBERT, M.D.

ECHOES AND NEWS.

No Yellow Fever in the State of Florida.—A letter from Dr. Leslie W. Weedon, health officer of the State of Florida, dated August 25, 1898, conveys the information that there has not been a case of yellow fever in the State of Florida this season.

Deaths among Spanish Prisoners.—The Spanish transport "Isla de Paney" from Santiago with a detachment of the surrendered Spanish troops on board has arrived at Coruna station. There were seventeen deaths on the steamer during the voyage.

A New Water-Supply for Camp Wikoff.—In accordance with the recommendation of Engineer-in-Chief Melville of the Navy, the distilling-ship "Iris" has been sent to Montauk Point. It is estimated that the vessel can furnish 60,000 gallons of distilled water per day.

The American Association of Obstetricians and Gynecologists.—The eleventh annual meeting of this Association will be held in the banquet-hall of the Monongahela House, Pittsburg, Pa., Tuesday, Wednesday, and Thursday, September 20, 21, and 22, 1898. In addition to an interesting program, consisting of scientific papers, a special feature of the meeting will be a presentation of pathologic specimens and their early histories with discussion pertaining to the same. Dr. Charles A. L. Reed of Cincinnati is president, and Dr. W. W. Potter of Buffalo, secretary.

The Army Hospital at Fort Monroe.—One pleasant oasis in the unfortunate condition of the Army hospitals is to be found at Fort Monroe Hospital. The inspector of the Red-Cross Society reports that the red-tape side of the management of hospitals is conspicuously absent, both in the mess-hall and in the sick wards. The men are a clean, happy-looking lot, most of them convalescent. The food given the men is good in quality and appetizingly cooked and served. The surgeons are men not too young to be without experience nor too old to have lost the distinct personal pride in the results of their treatment. They are capable as well as enthusiastic. No further assistance is required from the Red-Cross in this hospital.

Yellow Fever at Santiago de Cuba.—In the daily sanitary report to the Marine Hospital Service, dated August 18, 1898, the surgeon in charge says: "I have the honor to inform you that at the request of Military Governor-General Wood I visited the civil hospital to diagnose a suspected case of yellow fever. I made the examination and found a true case of the fever and had the patient isolated. It is the only case I have seen up to date. The mortality has gone down somewhat, as only forty-five deaths were reported to-day—civilians twenty-seven, military hospital fourteen, civil hospital four, Americans none. The Spanish troops are leaving now quite steadily, and we expect that by the end of the month they will all have departed. Many die on the way to the ships, and the majority embark in bad condition."

The Earnings of Medical Men in France.—M. Henri Berenger discourses in the *Revue des Revues* more or less pleasantly, but apparently with authority, on the intellectual proletariat in France. Here are some of his observations referable to the medical profession: There are in the whole of France, inclusive of Corsica but excluding Algeria, between 12,000 and 13,000 practising medical men

of whom 2500 live in Paris, the remainder being distributed throughout the provinces. As regards the metropolitan practitioners the following is the approximate scale of earnings: 5 or 6 earn between $40,000 and $60,000 per annum, from 10 to 15 earn about $30,000; 100 earn $10,000, 300 earn between $3000 and $6000, 800 earn between $1600 and $3000, 1200 earn less than $1600. Of the 10,000 provincial practitioners not more than half make a decent livelihood. Every year the various universities turn out about 1200 qualified doctors of medicine. The average duration of a practice may be set down between twenty and twenty-five years; it follows, therefore, that the production is twice as great as the demand. M. Berenger's statistics may be correct, but apparently he neglects to make allowances for the young medical men who are absorbed each year in the army, navy, and colonial services. Ten thousand practitioners for the whole of provincial France seems, moreover, to be anything but a liberal estimate, seeing that the number on the "British Medical Register" is at least three times greater.—*Lancet.*

Official View of Camp Wikoff.—President McKinley says: "What I saw of the care of the sick in the hospitals by those in charge and by the noble women engaged in that work was especially gratifying." Vice-President Hobart says: "I am agreeably surprised at the facilities I found at Camp Wikoff, particularly in the hospital service. I am not an army officer and have not a full experience in the judging of camps and camp systems, but it seems to me that Camp Wikoff is admirably adapted to army purposes at this time as a camp for recuperation. The hospital and hospital service seem to me perfect in appointments and system, and well adapted for the rapid recovery of the sick. Its location, its surroundings and its climatic conditions could not be improved. The men, with their trained nurses, cheerful surroundings, full medical equipment and good hospital service, will soon be ready to be sent home or to more permanent quarters. The country is rich enough, prosperous enough, and most anxious to give to these heroes every consideration, every comfort, and every luxury that they deserve or require." All of the rest of the Presidential party expressed themselves as delighted with the camp, especially Senator Proctor, who was enthusiastic over the location and all that he had seen in the hospital. General Wheeler in his official report dated September 3d says: "The distinguished physician, Dr. Senn of Chicago, asserts that the fever patients are much better taken care of at Camp Wikoff, both medically and in nursing, than in any other hospital he has ever seen, and the convalescents, as a matter of fact, are living luxuriously." General Shafter says: "Camp Wikoff is an ideal spot. If there is anything the matter with it, it must be under ground."

Report on Yellow Fever in Rio de Janeiro since the Year 1850.—Hon. Eugene Seeger, United States Consul-General to Brazil, in a recent report has the following to say regarding the occurrence of yellow fever at Rio: "The first appearance of yellow fever in Rio de Janeiro in December, 1849, undoubtedly constituted an event of graver importance than anything that has happened here before or since. From that time on this terrible scourge has exercised its pernicious influence on the development of the great Brazilian metropolis, which would otherwise be one of the most healthy of the world's great cities, as it certainly is one of the most beautiful. As far as shown by the official records, yellow fever has caused in Rio, up to July 1 of this year, the death of not less than 54,461 of its victims, 939 since January 1. The American brig "Brazil" from New Orleans, by way of Havana, brought the infectious microbes to Bahia (November 3, 1849), whence the disease was carried into Rio. It is a characteristic feature that the foreign-born inhabitants constitute not less than about eighty-five per cent. of the victims of yellow fever. Newcomers are all in great danger during the summer months. (Of the very few foreign diplomatic and consular officers living in Rio, there died during this season: The minister of Chile, the Haitian Consul, the Chancellor of the French Consulate, and the Chargé d'Affairs of Chile.) One of the results of this condition is the fact that during the fever season (from the beginning of December to the end of May) most of the foreigners live in the more or less remote suburbs in the mountains surrounding Rio, where they enjoy a comparative immunity from the plague. This, of course, involves a great expense and a great loss of time. The best known and most frequented of those health-resorts is Patropolis, since 1894 the Capital of the State of Rio de Janeiro, about 2500 feet above the level of the sea, in the Serra da Estrella. The diplomatic corps, with but few exceptions, and the majority of the foreign business men reside there with their families, most of whom have to make daily trips to Rio. The permanent injury caused to Brazilian commerce, trade, immigration, etc., by the yellow fever is enormous. It cannot be denied that the local authorities are doing a great deal within their limited financial means and under the peculiarly difficult ethnological conditions to fight this plague."

Railway Accidents.—The advance sheets of the Annual Report of the Interstate Commerce Commission for the year ending June 30, 1897, gives the following statistics: The total number of casualties in the United States to persons on account of railway accidents for the year ending June 30, 1897, was 43,168. Of these casualties 6437 resulted in death, and 36,731 in injuries of varying character. Of railway employees, 1693 were killed and 27,667 were injured during the year. According to the three general classes these casualties were divided as follows: Trainmen, 976 killed, 13,795 injured; switchmen, flagmen, and watchmen, 201 killed, 2423 injured; other employees, 516 killed, 11,449 injured. The casualties to employees resulting from coupling and uncoupling cars were, killed, 214; injured, 6283. The corresponding figures for the year ending June 30, 1896, were 229 killed and 8457 injured. The casualties from coupling and uncoupling cars were assigned as follows: Trainmen, killed, 147; injured 4698; switchmen, flagmen, and watchmen, killed, 58; injured, 1325; other employees, killed, 9; injured, 260. The casualties resulting from

falling from trains and engines were as follows: Trainmen, killed, 325; injured, 2726; switchmen, flagmen, and watchmen, killed, 32; injured, 357; other employees, killed, 51; injured, 544. The casualties to the three general classes of employees mentioned caused by collisions and derailments were as follows: Trainmen, killed, 250; injured, 1327; switchmen, flagmen, and watchmen, killed, 11; injured, 74; other employees, killed, 42; injured, 251. The total number of passengers killed during the year under review was 222, injured 2795. Ninety-three passengers were killed and 1011 injured in consequence of collisions and derailments. Other than employees and passengers the total number of persons killed was 4522; injured, 6269. Included in these figures are casualties to persons classed as trespassers, of whom 3919 were killed and 4732 were injured. From summaries showing the ratio of casualties, it appears that 1 out of every 486 employees was killed and 1 out of every 30 employees was injured during the year. With respect to trainmen, including enginemen, firemen, conductors, and other trainmen, it appears that 1 was killed for every 165 employed, and 1 injured for every 12 employed. One passenger was killed for every 2,204,708 carried, and 1 injured for every 175.115 carried. Basing rates upon the number of miles traveled, it appears that 55,211,440 passenger-miles were accomplished for each passenger killed, and 4,385,309 passenger-miles for each passenger injured.

CORRESPONDENCE.

A POSSIBLE CURE FOR NERVOUSNESS.

To the Editor of the MEDICAL NEWS.

DEAR SIR: As the wife of a physician I have become convinced that much of the nervousness of the American people comes from the fact that two persons occupy the same bed. Again and again in a practice of twenty years have the beneficial effects of separation been noted. The stronger body always draws from the weaker. Sometimes the wife, sometimes the husband is the sufferer.

"Sleep with her, doctor," said the husband of a patient, "I couldn't sleep with her any more than I could with a catamount." His wife was afflicted with herpes zoster. Said the wife of a clergyman, herself the picture of health, "No, I cannot sleep with my husband, I seem to take all his strength and he wakes in the morning completely exhausted." Mrs. A., a physician's wife, became so nervous that she was on the verge of insanity. Dr. A. would lie by her side in uneasy, heavy sleep, dreaming of driving his horses and visiting his patients; or, worse still, grating his teeth and snoring. The wife confessed to me that she thought of her coffin with longing as a place that would be dark and still and where no one would "joggle" her. Two years ago Mrs. A. began sleeping on a cot at the bedside leaving her husband the bed "to thresh around in." At this writing she is almost cured of her nervousness and the doctor frequently answers night calls without her knowledge. Two sisters, the Misses F., were separated with beneficial results; also the Misses W., sisters; also, the Misses M., sisters.

The Misses D., sisters, refused to be separated. They continue to look like a couple of sick owls. These are only a few of the cases that have come under our observation. In the case of pregnant women and delicate children it is only repeating what is well known to say that they should sleep alone.

If the doctor be a man of tact, and if, in the case of man and wife, the bed and not the room be changed, people will almost always be guided by the advice of a physician in whom they have confidence and whom they respect and love. The family physicians of our country are the guardians of the public health and they should educate our people on this matter till it is as well understood as the fact that it is dangerous to health to have a dirty dishcloth or to drink impure water.

L. C. FAIRMAN,

LYNDVILLE, N. Y., August 25, 1898.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

GERMAN DOCTORS AND SPECIAL STREET PRIVILEGES IN URGENT CASES—A BOOM FOR VEGETARIANISM AND A RECENT LEGACY TO THE CITY OF BERLIN—CONGRESS FOR THE ADOPTION OF MORE HYGIENIC CLOTHING FOR WOMEN.

BERLIN, August 29, 1898.

A VERY interesting movement among German medical men just now is the effort to secure for doctors when on urgent calls the right of riding and driving through city streets as privileged persons. The first step in this line came at Augsburg, in South Germany, some time ago. Doctors who ride bicycles were, when on hurry calls, allowed to display in addition to their license number, a tag bearing a red cross upon a white ground. This secured them practically the right of way over all other vehicles and the police were instructed to aid them in making their rights in the matter effectively available. Other German towns adopted the same regulation, which promises to become universal in Germany.

In Berlin, as in some other German cities, in order to avoid accidents, bicycles are forbidden on certain of the busier streets. The regulation is a most salutary one and has saved Berlin from frequent sad accidents that occur elsewhere. Of late there has been question in police circles of still further restricting bicycling by forbidding the wheels on other streets. As this necessitates many a detour and at times even frequent dismounting, Berlin doctors have asked for the privilege in hurry calls of riding on all streets. So far their request has always been refused, but it is confidently expected that now, with the example of smaller towns as models of the feasibility of granting such privileges, the Berlin doctors will secure the favor as soon as the further closing of streets to bicycles goes into effect.

Another privilege asked for several times by Berlin doctors, but so far not granted, seems likely now to come up for favorable reconsideration. Street-cars in Berlin, as in most places on the Continent, have a certain number

of places for passengers, more than this the conductor is not allowed to take fares for. It sometimes happens then that at busy hours of the day three or four cars may pass a given point, each containing its full complement of passengers. It would be very easy to carry one more (the proverbial capacity of a street-car is just one more I believe) because ample room is accorded each passenger in the original allotment of space for passengers. Doctors who are not infrequently delayed on urgent cases perhaps by the existence of this otherwise very praiseworthy regulation, have demanded to be allowed the privilege of being carried as extra special passengers. As I have said, it seems at present as though the privilege would be accorded them. A further movement in this line of street privileges is that permitting doctors' vehicles of all kinds the right of way on displaying some suitable emblem that indicates an urgent call. German medical men are, as may be judged from these movements, thoroughly alert to secure the privileges their duties to patients demand and the spirit of professional cooperation which is at the bottom of the movements is thoroughly commendable and deserves the study and imitation of medical men elsewhere who feel the need of corresponding privileges.

At the last meeting, before the university vacation, of the Association of Visiting and Resident Physicians to the Charité Hospital, Berlin, there was a discussion by the assistant director of the hospital of the terms of a recent legacy to the city of Berlin. The Professor of Law at the University of Berne in Switzerland, Dr. Julius Baron, a former resident of Berlin, left his estate, a large one, to the city of Berlin for the purpose of establishing a home for orphans and abandoned children. To the legacy, however, is attached the condition that the children shall be brought up according to the principles of vegetarianism. By vegetarianism, the maker of the bequest explains that he means that they shall not be fed on any material that comes from dead animals of any description. Flesh and fish are to be absolutely excluded from their dietary, though products of living animals, butter, milk, cheese, honey, eggs, etc., may be permitted. The main articles of food, however, are to come from the plant kingdom.

The legacy was absolutely dependent on the conditions mentioned. The funds were to be managed entirely separate from all other city funds and were bound up by their legal bequeather, as the funds of a ward in chancery, and only the interest actually accrued was to be used, so that absolute provision was made for the perpetuity of the new institution which was to bear the name "Professor Baron's Vegetarianisches Kinderhaus" (vegetarian home for children).

In the discussion at the medical meeting at the Charité it was considered that it would be inadvisable for the city of Berlin to accept the legacy under the conditions named. Vegetarianism was to be looked upon only as a fad whose devotees even in adult life run no inconsiderable risk of serious constitutional affections owing to uncalled for interference with the normal metabolic requirements of human beings as at present constituted. The question of children being brought up on any such one-sided diet was thought to be a dangerous and almost inevitably unsuccessful experiment that would result in weakened constitutions and enfeebled health. The magistrates of the city of Berlin thought differently from the doctors, or perhaps the large legacy dangled before the eyes of the city fathers thus temptingly was too substantial an argument against any merely medical opinions, and the legacy was accepted with its conditions.

There will be an excellent chance then in a few years to study the effect of absolute vegetarianism from the earliest years upon human beings. It is to be hoped that the gloomy forebodings of the doctors for the result of the trial will not be fulfilled. There is certainly in the light of our present knowledge of metabolism, an air of experimental research about it that would seem to make it unjustifiable. This was not, however, the idea of its founder, for years himself a confirmed vegetarian and a firm believer in the possibilities of vegetarianism to eradicate many of the physical evils, and as most vegetarians, some of the moral evils too, that afflict mankind.

A very interesting event, for vegetarians at least, has occurred since the first announcement of the bequest and its terms. Just at the beginning of July the Turning Club of Berlin held a bicycle contest, a so-called *Tages-Dauermarsch*, a continuous day's travel, the contestants in which to get a place, must have completed 15 German miles (112.5 kilometers, about 70 English miles) in 18 hours. The contest was won by a vegetarian who made the distance in the record time under the conditions (we quote German papers) of 14 hours and 11 minutes. He arrived at the finish in comparatively good condition, fresh and not exhausted. Of 23 other contestants 8 were vegetarians and 6 of them were the first in the contest and made the distance within the time limit. Only 1 of the 15 non-vegetarians made the distance within the time, all the others having to give up. The winners had no special training for the event, but were like the other contestants, ordinary members of the Turning Club. During the run the vegetarians consumed only sweet fruits, fresh salads, and some bread and milk. So long as the meat-eaters remained in the race the difference as to the two classes of contestants in the matter of exhaustion was very striking and in favor of the vegetarians, who looked fresh and unruffled when the others were already playing out.

The event has attracted a great deal of attention in Germany. The army officials have consulted the winner and his friends as to their diet and habits and have instituted a set of investigations as to their power of standing military fatigue on a vegetable diet. So far the results are said to be surprisingly favorable to the energy that can be developed on a dietary so supposedly insufficient. The result has been a boom to vegetarianism otherwise in Germany, and the number of vegetable restaurants has notably increased in Berlin. Though the idea seems so foreign to German notions, there have always been some, while those that exist are much more frequented than before.

From the 3d to the 18th of September the Association for the Improvement of Women's Clothing and of Hy-

giene for Women holds an exposition in Berlin, at which the recent models and sketches for healthful, convenient, and graceful garments for women are to be exhibited and the latest suggestions in this line discussed. Prominent medical men and medical societies have been especially invited to give their attention to the subject. Despite the fact that most young German women during their turning exercises wear trouser suits that are extremely comfortable and certainly not ungraceful, the problem of easy hygienic garments for women, that shall not be dirt- and dampcatchers is no nearer solution than it is with us.

Of late female enthusiasm for the bicycle in Germany has made sad inroads on the hidebound conservatism of the older generation of German women. It really begins to look as though the new sport and exercise is going to do more to hinder some of the hideous sacrifices to beauty of form and grace that the bigoted worship of the goddess Fashion has so far demanded and obtained from her votaries than all the protests of medical men and common sense for centuries. Zola, in his latest book, "Paris," has one of his female characters express the opinion that the bicycle will lead to the doing away with skirts, especially the long and clinging garments that are such a hindrance to movement, are so dirty, such scavengers of what is vile and contagious upon the pavement and yet are certainly anything but ideally graceful. There is the added Zolaesque touch that the exposure of ankles and even calves on the street cannot be so dangerous as the exposure of breasts in decolleté dresses in the ballroom, but that, of course, may be a matter of the point of view.

In any case medical men cannot but welcome modifications of women's clothing that allow freer movement and bring with them freedom from abuses that have been the subject of medical protest for years. The results of the present exposition will be watched with interest by German medical men, for German women with ideas have a way of taking the bit in their teeth and overleaping barriers, and something practical may result.

SOCIETY PROCEEDINGS.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Fifteenth Annual Meeting, Held at the Maplewood Hotel, near Bethlehem, N. H., August 31 and September 1, 1898.

FIRST DAY—AUGUST 31ST.

BEFORE the reading of the President's address fitting tributes were paid to the memory of Dr. T. D. Bratton of Augusta, by Dr. Otis, of Dr. Harrison Allen of Philadelphia, by Dr. R. G. Curtin, and of Dr. William Pepper by Dr. J. H. Musser.

After welcoming the members of the Association the President, DR. E. O. OTIS of Boston, delivered an address on Avenbrugger and Laennec, the discoverers of percussion and auscultation. He thought it eminently proper that an association devoted largely to the consideration of diseases of the chest should honor the memory of these illustrious men by reviewing their lives and work. He gave an account of Avenbrugger's life and his great work on percussion. His life, modest like that of most great men, was spent in enthusiastic devotion to his profession and in love and service to his fellow men. His "Novum Inventum" was revived by Corrisart in 1808 by a French translation, with copious commentaries and its inestimable value shown.

The incident leading to Laennec's discovery of auscultation was given. The development of the discovery was traced and the making of the stethoscope. Laennec's whole life was absorbingly devoted to professional pursuits. He was absolutely true and unselfish in his professional aims. In the diagnosis of diseases of the chest he was universally acknowledged to be without a rival.

DR. FREDERICK I. KNIGHT of Boston read a paper on

SOME ERRORS OF GENERAL PRACTITIONERS IN DEALING WITH CASES OF PULMONARY TUBERCULOSIS.

He referred to certain common errors which he thought might be diminished if his remarks were endorsed by the members of the Association. The errors to which he especially called attention were:

1. Failure to make an early diagnosis, which is usually easy since the discovery of the tubercle bacillus.

2. Failure to admit the gravity of the situation the moment it is discovered, and to put the patient at once in the best possible condition for recovery. Niemeyer used to say that the danger of a consumptive patient was "that he became tubercular." In the light of modern pathology Dr. Knight would say that the danger of a tubercular patient is that he became consumptive, *i.e.*, subject to secondary infection. There is often failure to sufficiently impress the patient also with the gravity of the situation to secure his thorough cooperation in the effort for his recovery.

3. While temporizing, giving nauseating medicines, too much alcoholic stimulants and prescribing exercise, etc., which only hasten the decline.

4. Sending patients away from home who have only a few months or weeks to live, or who have not sufficient money to live properly away from home long enough to do them any good; also, exercising insufficient care in the selection of a residence for those who are suitable for change.

5. Insufficient professional supervision of patients, who always require constant watchfulness whether at home or at some climatic resort.

DR. VINCENT Y. BOWDITCH of Boston read a paper on

THE RESULT OF SOME RECENT EXPERIENCE WITH PHTHISICAL PATIENTS.

He said that in his examination of patients he had been frequently impressed with the fact that one or two of what he believed to be the most important features in diagnosis, or rather prognosis, had apparently been overlooked by the physician in attendance. Although ordinarily comparatively easy to make a diagnosis of pulmonary tubercular disease, in cases where dulness

upon percussion, changes in the respiratory murmur and even râles are lacking—cases in which the power of diagnosis and prognosis are taxed to the utmost—he had frequently found that the general practitioner had not paid sufficient attention to what he deemed the most important symptoms, the quality of the pulse, the temperature, and condition of the digestive organs. Post-mortem examinations had frequently shown that in patients with few physical signs in the chest, but with a weak, rapid pulse, more or less elevated temperature and poor condition of the stomach, there had been an almost universal dissemination of tubercle, without, perhaps, marked breaking down of tissue. These unfavorable conditions of the pulse, temperature, and digestive organs he believed entirely inconsistent with a truly *incipient* form of tubercular disease, even when the physical signs in the chest are few or entirely lacking.

He referred to and emphasized his observations in a previous publication "A Plea for Moderation in Our Statements Concerning the Contagiousness of Phthisis" (*Boston Med. and Surg. Jour.*, 1896). While appreciating fully the teachings of bacteriology, the importance of absolute cleanliness in connection with phthisical patients, and attention to the general health of those in attendance, he maintained that this care could be kindly and wisely given without causing a spirit of terrorism and without making such sweeping and unjustifiable statements as that "all homes for consumptives are a source of danger to the surrounding community."

He mentioned the statement of Flugge of Berlin (*Deutsch. Med. Wochenschrift*, October 15, 1897) regarding the possibility of bacilli being carried in small droplets of mouth fluid into the air during the act of coughing, and believed that we should wait for further proof before accepting this extreme theory.

The papers of Drs. Knight and Bowditch were discussed jointly. DR. DIDAMA referred to one of the errors mentioned by Dr. Knight of sending patients to Colorado and elsewhere who are too far advanced in consumption, and said it would seem that some physicians send them away to escape signing the death certificate. Yet there have been instances of patients who have had many hemorrhages being benefited by residence in Denver. He questioned whether when the disease is far advanced, and the patient nervous about his condition it is right to tell him frankly the absolute truth. Regarding the remedies, he said consumptive patients are expected to improve as the medicine is changed, or as they changed the doctor. Even within two or three days of their death there is an improvement in their symptoms. He was glad Dr. Bowditch had spoken of the too common feeling that consumptives are social lepers. He did not believe there is any particular danger in having a friend call who had a consumptive cough.

DR. WALKER of Philadelphia agreed heartily with the sentiments of both papers.

DR. R. G. CURTIN of Philadelphia was much pleased with Dr. Knight's remarks in regard to the old-fashioned treatment of tuberculosis. He agreed with the remarks of Dr. Didama that physicians are often to be blamed for sending patients away when they would be better at home, yet there are times when the advice is unheeded until the disease is too far advanced.

DR. J. H. MUSSER of Philadelphia thought it one of the most difficult things in medicine to decide which patients should be sent away, and which retained, and cited the case of a patient in whom general tubercular infection had apparently advanced to extreme weakness and emaciation, whom he had advised to go to the Adirondacks. His stay there under medical treatment had resulted in arrest of all manifestations of the disease.

DR. HART of Denver said that the papers of Drs. Knight and Bowditch expressed exactly what he had wanted to hear. He said too often patients arrive at Denver in about the condition in which they are finally sent home, with every indication of advanced tuberculosis, and that it is a very difficult thing for the physician at a health-resort to manage these patients.

DR. CHARLES E. QUIMBY of New York said that he had nothing to say personally, except that which Dr. Bowditch and Dr. Knight felt their kindness of heart prevented them from saying, and had requested him to say, that while their papers were directed to the general practitioner, they were intended for us all.

DR. COLEMAN, although having had but few cases illustrating points brought out in the papers under discussion, believed that the early appreciation of the tubercular lesion is the key to the cure and that where a proper physical examination is made many of the errors will be avoided. He had made it a rule of his life to make a thorough physical examination of all patients coming to him.

DR. BEVERLEY ROBINSON of New York said that while he agreed that a great many individuals are not examined accurately enough and the diagnosis not settled sufficiently soon nor proper and judicious treatment not followed up at all times as it should be at the time most favorable, he believed that with a better understanding of the disease, the better education of our medical colleges, this error will be much less frequently committed.

DR. KNIGHT said, in closing the discussion, that in the treatment of tuberculosis he thought the excessive use of syrups should be avoided as much as possible.

SECOND DAY—SEPTEMBER 1ST.

DR. JUDSON DALAND of Philadelphia read a paper, entitled

A CASE OF DISSECTING ANEURISM OF THE THORACIC AORTA RUPTURING INTO THE PERICARDIAL SAC AND CAUSING IMMEDIATE DEATH.

Dr. Daland said that the rarity and completeness of this lesion, the evidences of complete reparation of a similar lesion above the former one, and the extraordinary changes in the heart and aortic valves, together with the unusual mode of death led him to call attention to a case which he described in detail. The patient was a man thirty-eight years old, whose personal and family history was unimportant except that he used whisky moderately. He sought relief from edema of the legs, headache, and diarrhea. His symptoms improved under absolute rest,

eight ounces of buttermilk every two hours, and Basham's mixture. He gradually resumed a mixed diet and did not again seek medical aid for four years. During this interval he returned to the use of whisky, averaging two pints a day. Examination showed marked arteriocapillary fibrosis, and considerable increase of hypertrophy of the left heart with a faint systolic murmur. Two years previously he had suddenly experienced complete loss of muscular power without other symptoms. The urine presented a moderate amount of albumin and a few hyalin tube casts. Three months later he complained of excessive muscular weakness and fear of death, accompanied by headache and morning vomiting. In a few weeks he suddenly developed left hydrothorax with excessive frequency and irregularity of breathing, rapid and irregular heart action and cyanosis which were relieved by thoracentesis. Five years after the first examination ordinary evidences of cardiac failure showed themselves and he died suddenly in December of the same year apparently from cardiac failure. The diagnosis was marked arteriocapillary fibrosis, enormous left ventricular hypertrophy and dilatation, with mitral regurgitation and chronic interstitial nephritis alcoholica.

The autopsy showed one-half inch above a recent rupture of the aorta, a linear spot measuring one-half inch in length and parallel to the long diameter of the artery. It communicated directly with the pericardial sac and was the immediate cause of death. There was evidence that the dissecting aneurism extended for an unknown distance into the thoracic aorta.

DR. BEVERLEY ROBINSON of New York read a paper, entitled

CLINICAL NOTES ON ASTHMA AND ITS TREATMENT.

The essayist said that among the diseases which the practitioner is called upon to treat none is of greater interest than asthma. This interest is partly due to its etiologic obscurity. The cases of so-called nervous asthma in the speaker's experience have been infrequent, and he believed that when we are better informed examples of purely functional asthma will perhaps no longer be described. He believed that despite the existing nervous irritability the asthmatic attack would rarely occur were there not other discernible cause which more advanced researches will reveal. Conditions of the blood are often ignored. Malarial toxemia is frequently present and yet overlooked. It is wisdom to act in accord with its recognition. If there be a sudden chill followed by rise of temperature and sweating and if at the time of the chill and previous to the giving of quinin internally a skilful microscopic blood examination be made the plasmodium malariæ should be found. For an asthmatic attack of probable malarial causation he advised increasing doses of Fowler's solution of arsenic to its physiologic effect; if the bowels are constipated and liver inactive, Warburg's extract in 5-grain doses three or four times daily; if anemia be present, quinin, iron, and arsenic in a suitably formulated pill, the following being a favorite with the speaker: 1 grain of reduced iron, 2 grains of sulphate, or preferably the muriate of quinin, and $\frac{1}{60}$ to $\frac{1}{30}$ of a grain of arsenious acid, three times daily after meals. Of course, if the attack be severe, one should employ antispasmodic remedies, and also permit patients to smoke and inhale from a cigarette d'Espic, datura Tatula (Savoy and Moore), or of simple niter paper. As a last resort, the inhalation of a small quantity of chloroform or a hypodermic of morphin and atropin may become our only satisfactory help.

He was in accord with those who find in the constitutional conditions of gout and rheumatism an underlying influence of great power in causing nervous irritability and characteristic appearances of the throat, and where there is a clear history of these affections one may infer in many instances that the asthmatic attack is of similar origin.

As to the reflex causes of asthma, when one finds in the nose and throat morbid conditions one cannot be satisfied with the care of the patient unless operative interference be undertaken to modify or remove these evidences of disease. While this is true, it should be admitted that several prominent throat specialists have exaggerated the diseased conditions of throat and nose as causative in producing asthmatic attacks.

In chronic gastric catarrh, brought on by errors of diet, or alcoholic habits, frequently lavage of the stomach and a regulated regimen have afforded great relief in the asthmatic seizures. In the consideration of bronchitic cases of asthma with some development of emphysema one is confronted with questions clinically most difficult to decide. When the bronchitis is clearly defined and the secretion slight one's main effort should be to stimulate the latter by appropriate means, and here small repeated doses of ipecac, tartar emetic, grindelia robusta, chlorid of ammonia, and iodid of potassium are very useful. Where the bronchitis is also evident and yet there is much bronchial secretion, belladonna or atropin must be combined in small or moderate doses with the drugs previously named, or should be given with a little camphor and quinin in capsule or tablet form, or what is often preferable, alone, until their physiologic effect is manifest. When the emphysema and bronchitis are clearly defined, and when the asthma is also pronounced, one must have recourse for temporary results to inhalation of the fumes of the antispasmodic cigarettes, the repeated use of oxygen gas, or the administration of Hoffman's anodyne, alcohol, hot coffee, capsules of ether, or chloroform.

Where in connection with the previous conditions there is evident cardiac distention one must have recourse to nitroglycerin or the nitrites, or to a soluble salt of caffein (salicylate), either by the mouth, or hypodermically. Occasionally blood-letting, by bleeding from the arm, or the use of leeches, or wet cups to the chest or epigastrium will afford more or less lasting relief.

The question of change of locality is one difficult to solve. Personally, the speaker was inclined to believe, after considerable experience, that the climatic conditions which shall prove best for subacute or chronic bronchitis are also those best suited to the bronchitis when complicated with asthma.

DR. A. JACOBI of New York read a paper on

ERGOT IN CHRONIC MALARIA,

which will appear in a later issue of the MEDICAL NEWS.

A paper by Dr. R. C. Newton of Montclair, entitled "A Preliminary Report on Sixty-five Cases of Malarial Fever in Relation to Their Contiguity to Certain Brooks," was read by title. A paper by Dr. J. C. Wilson of Philadelphia, entitled "The Natural History of Pulmonary Tuberculosis," was read by title. Papers by Drs. Theobald Smith of Boston and J. C. Mulhall of St. Louis were also read by title. The paper by Dr. Andrew H. Smith of New York on "Oxygen Inhalations in Acute Pulmonary Affections," will appear in a later issue of the MEDICAL NEWS.

DR. J. M. ANDERS of Philadelphia presented a paper on

SANATORIA FOR THE CONSUMPTIVE POOR,

showing the extent and urgency of the needs presented by the large class of phthisic patients, and the value of special hospitals and sanatoria for their treatment, and discussed the discrimination of the cases among the lower class into three groups, and the remedy for each. He stated that statistics prove pulmonary tuberculosis to be proportionately far more common and inauspicious among the lower than among the higher classes, and that the almost absolute lack of proper facilities for the poor afflicted with pulmonary tuberculosis is a most potent factor in maintaining the large death-rate. He believed special hospitals to be superior to separate wards in general hospitals for the treatment of cases of pulmonary phthisis, and quoted a reduction of fifty per cent. in the mortality-figures when special hospitals are used for the disease. He believed sanatoria near large cities to be even better than the special hospitals in densely populated centers, and climatic sanatoria, in the earlier stages of the disease, have showed results surpassing those of all other known methods of treatment.

For patients hopelessly afflicted he advocated every comfort, such as could be furnished by special hospitals in healthful urban localities. For the incipient cases among the pauper element sanatoria located in close proximity to large municipalities, with special reference to purity of atmosphere and with protection by natural elevations or woodland from chilly blasts, should be provided. Patients with phthisis pulmonalis among the middle and working-class, or those having small means, would be compelled to depend principally upon private philanthropy and probably semi-State institutions. He approved of the combined sanatorium and climatic treatment and believed it could be made almost self-supporting.

DR. E. R. BALDWIN of Saranac Lake, N. Y., read a paper on

INFECTION FROM THE HANDS IN PHTHISIS.

The paper described the results of an examination of the hands of twenty-eight patients by washing their fingers in a sterilized, weakly alkalin solution. Inoculation of the washings into guinea-pigs was successful in producing tuberculosis from ten out of fifteen patients, mostly in advanced stages of the disease, and many of whom expectorated into handkerchiefs. Out of twenty-four cases in which the centrifugated washings were examined microscopically for bacilli, six were positive. The author regards the danger of infection from the hands as small unless it shall be shown that the disease is more frequently acquired through the mouth, but urges more general use of cheap, destructible handkerchiefs, and frequent ablution when cuspidors are impracticable.

DR. FRANCIS H. WILLIAMS of Boston read a paper, entitled

APPLICATION OF THE X-RAYS IN THE DIAGNOSIS OF TUBERCULOSIS.

The paper presented a general statement of the medical applications of the X-rays. One of its most useful applications is for diseases in or contiguous to the thoracic cavity, and in that connection the speaker considered the subject. Diagrams were shown which were made by transferring outlines which the author had drawn on the skin of patients while looking through the fluoroscope, to a skeleton outline copied from one of Luscka's plates. The position of the diaphragm and heart were shown as in full inspiration, and the position in expiration. In health it is seen that the diaphragm has a wide excursion between the extremes of respiration, and that the heart also changes its place. The difference in the brightness of the lung area between expiration and full inspiration may be perceived by means of the fluoroscope. This shows how conditions involving congestion, as in early tuberculosis or in some form of cardiac disease, may alter the appearances in the fluoroscope. The diagram of health was used as a key to the others and comparisons made with it and the diagrams of the various diseases. Thoracic aneurisms may now be always recognized with certainty. Further symptoms due to aneurism are sometimes ascribed to other diseases and an X-ray examination is required to establish the diagnosis.

Diagrams were exhibited showing the excursions of the diaphragm, the position of the heart, and the appearances in emphysema, pleurisy, pneumonia, pulmonary tuberculosis, pneumohydrothorax, and pneumothorax. As the X-ray examinations in pulmonary tuberculosis come more into use the speaker was convinced that the presence of the disease will be recognized earlier. A number of cases were cited, chosen to illustrate some of the ways in which X-ray examinations might be useful in pulmonary tuberculosis.

DR. E. FLETCHER INGALS of Chicago presented a paper on

THE VALUE OF SYSTEMATIC PHYSICAL TRAINING IN THE PREVENTION AND CURE OF PULMONARY DISEASE.

In considering this subject he called attention to the fact that one of the most common observations made by medical men is that the long, narrow, flat-chested person is the one most liable to the development of tuberculosis, and that in persons presenting this form of chest the chances for recovery are reduced to a minimum. He thought the observance of systematic physical training in aiding to develop the respiratory muscles, thoracic walls, and pulmonary capacity would be of much service in pre-

venting tuberculosis and also in curing it in its early stages. Since collapsed air-cells furnish a most favorable nidus for the development of tuberculosis, he urged that measures should be adopted to expand the lungs and speedily bring the air-cells into the best possible working condition. He believed it probable that the lungs are rendered more susceptible to the tubercle bacilli and their toxins by an early tubercular localized anemia which diminishes the nutrition. Of the eighty per cent. of the human family said to be affected by tuberculosis the majority recover, and the mortality is not more than twelve per cent. If, as has been stated, the presence of the disease had only been found at autopsy, after death from other causes, and in those who had recovered it had made but little progress, he thought it a duty to recommend measures which would strengthen the resisting power of the lungs. As a means of prophylaxis his first measure would be to instruct the patient in deep breathing. He attached the greatest importance to careful physical training, believing that the long, narrow, flat chest might be materially improved in form and circumference, and Nature given a greater chance to throw up barriers against the disease.

DR. IRWIN H. HANCE of Lakewood, N. J., presented a paper on

A SINGLE TEST OF THE VIRULENCY OF SPUTUM KEPT MANY MONTHS.

He referred to the virulency of the tubercle bacilli as demonstrated by the clinical pictures of pulmonary tuberculosis and the resistance of these germs against development. He reported the experiment of Stone, in 1891, in which the tubercle bacilli retained their form and virulency for three years. Similar experiments made by himself were described with results so different as to justify the conclusion that the tubercle bacilli were no longer viable, and the following queries were presented: Whether sputum which remains in a liquid state for a long time develops toxins inimical to the life of the tubercle bacilli? Whether the result would not have been different had the sputum been more virulent in its character, and taken from a case of acute, active tuberculosis? Whether if sputum dries more rapidly does it retain its virulency longer? All such queries he believed could only be answered by further experimental work.

DR. J. E. STUBBERT of Liberty, N. Y., read a paper, entitled

SOME STATISTICS UPON SEROTHERAPY IN TUBERCULOSIS,

giving a short history of experiments in antitubercle serums with the theory of its action and the methods of preparation. The action of the tubercle serum is indirect rather than germicidal. Partial immunity has been secured by de Schweinitz in guinea-pigs. The serum developed in horses has been found more effective than that from other animals. The amount of clinical material furnished he believes insufficient to justify evidence in the good results claimed for different serums. The serum manufactured by the United States Government under de Schweinitz is his preference, and the following results are given of 82 patients treated by this serum: Expectoration decreased in 82 per cent., appetite improved in 81 per cent., weight gained in 78 per cent., physical signs improved in 82 per cent., temperature decreased in 49 per cent., bacilli disappeared in 13 per cent., apparent immunity established in 21 per cent., bacilli decreased in 35 per cent., cough decreased in 79 per cent., generally improved in 85 per cent.

The use of the serum is indicated only in incipient cases, although temporary reduction of temperature has been obtained in advanced cases in a few instances. He has used the antistreptococcic serum to reduce cases of mixed infection to those of simple, that the action of the antitubercle serum might act more freely. His experience in this, however, has been insufficient for definite conclusions. No danger attends the injections. The advantages claimed are absence of interference with digestion; in cases in which the bacilli have disappeared they have done so while the sputa was still present; no report of relapses even in patients returned to their former environments.

The writer is not a thorough advocate of serotherapy, adhering still to climatic, hygienic, and dietetic treatment in all cases, but believes that sufficiently good results have been obtained to justify further research in this direction, better pursued in sanatoriums.

DR. HENRY P. LOOMIS of New York read a paper on

THE PRETUBERCULAR STAGE OF PHTHISIS, OR THE CONDITION WHICH ANTEDATES TUBERCULAR DEVELOPMENT, AND SOME AIDS TO ITS DIAGNOSIS,

claiming that there is a condition precedent to the initial development of tuberculosis which should be called the pretubercular stage. The signs are to be looked for in the corpulence of the individual, in the chest conformation and vital capacity, in the constitutional condition, and in the character of the pulse. It is possible in many cases, especially in chloro-anemics, to diagnose phthisis before the appearance of physical signs or the tubercle bacilli in the sputum. Weight, respiratory capacity, and chest measurement have no value in establishing the possibilities of the development of phthisis in themselves but must be considered in relation to the height of the person, when they furnish three important aids to diagnosis. Corpulence is obtained by dividing the weight by the height expressed in feet. Normally in a man it should be 26; in a woman, 23. Chloro-anemia and persistent and unexplained disturbances of the digestive system are symptoms of the pretubercular stage. There are two characteristics of the pulse found in the pretubercular stage and early stage of phthisis: (*a*) change of position has practically no influence on its rhythm; (*b*) relative feebleness of arterial pressure.

DR. CHARLES E. QUIMBY of New York read a paper, entitled

A PLEA FOR MORE ACCURATE METHODS OF RECORDING THE RESULTS OF PHYSICAL DIAGNOSIS OF THE LUNGS.

He said that this latter half of the Nineteenth Century has come to be known, no less in medicine than in other

branches of science, as the age of progression. We as physicians may rejoice with peculiar satisfaction that in medicine the change has not been solely one of technic and application but that in many lines at least we have started upon a strictly scientific basis. While surgery may perhaps present to the layman the most abstrusively attractive illustrations of exactitude in methods and results, the more critical and closely analytical professional mind must admit that the broadest and most potentially valuable advances in medical science of our own time have been in the domain of medicine. The very word, physical diagnosis, presupposes definiteness and certainty, claiming as it does for a basis the best developed of limited sciences.

The purpose of the paper was to outline some modest attempts at recrystallization and to urge the adoption of a scientifically accurate method of recording the results of physical examinations of the lungs. That it is possible to make such a record, and in such manner as will render it a direct index to the amount of disease and a standard for future reference, he was fully convinced. Complete physical record of respiration at any given point comprises: (1) the pitch note of the trachea; (2) that of inspiration and expiration, and (3) the relative length of these two sounds expressed as a fraction. For example, respiration at point *a*, left chest; tracheal note *g*; inspiration, *f*, above; expiration, *e*, between; rhythm, ¾.

It is understood that the foregoing statements refer solely to respiratory sounds as affected by uniform changes in the chest and exclude localized excavations, although the same principles may be applied to these conditions. Thus respiratory with percussion sounds afford an absolutely scientific, accurate record of pulmonary conditions and changes. It were superfluous to dilate upon the value of such records in cases remaining under our own supervision or for such as we desire to send to other climates and places in the care of other physicians.

THE DISTRIBUTION OF PULMONARY TUBERCULOSIS IN NEW JERSEY

was the title of a paper by DR. GUY HINSDALE of Philadelphia, who exhibited a map on which the various regions of the State were platted so as to show the different degrees of prevalence of the disease. He said that the distribution of tuberculosis in this State corresponds in great measure with well-known facts relating to the disease. Contrasted with New York and Pennsylvania New Jersey does not show such wide variations. In the former State there are counties in which the disease is three or four times as rare as in the same densely populated districts. In New Jersey the counties in which the larger cities are situated show a prevalence only twice as great as in the sparsely settled regions. Hudson, Essex, and Mercer counties, in which are situated Jersey City, Newark, and Trenton, have from four to five hundred persons living to one death from phthisis, while Sussex, Warren, Hunterdon, and Gloucester counties, have between eight and nine hundred persons living to one annual death from phthisis. The remaining counties were platted to show the three intermediate grades. Elevation above tide does not play a part as it apparently does so plainly in the case of Pennsylvania. In New Jersey on the other hand, one of the counties, Gloucester, in South Jersey, is quite low, but it belongs to the group in which tuberculosis is least prevalent. It is, at least, one of the three counties in which the disease is prevalent. In the northern and northwest part of New Jersey the surface is more diversified, reaching elevations of about 2000 feet. The soil in the northwestern half of New Jersey is largely red clay with out-croppings of sandstone, and in the northeastern portions trap rock. In Essex County there are positive evidences of a great prehistoric lake, called Lake Passaic. Its southern portion is the present site of a great swamp. The soil of the southern half is principally sand which in places like Lakewood reaches to a depth of six or seven hundred feet. But the character of the soil would seen to have little if any influence in the present instance in modifying the presence and distribution of tuberculosis. It is density of population which bears the closest relation to the distribution of tuberculosis in New Jersey. A diagram was shown in which this relation was characteristically represented. The counties which have less than one acre to each inhabitant have a high death-rate from tuberculosis, while Atlantic, Sussex, and Cape May Counties, which have from ten to twenty-two acres per inhabitant, have a low death-rate. Three of these are maritime counties. Sussex has the lowest death-rate of the four, and of all of the counties in New Jersey it is farthest from the sea and embraces the highest land in the State. It adjoins Pike County in Pennsylvania, one of the wildest and most heathful in that State.

The following officers were elected for the ensuing year: President, Beverley Robinson of New York; vice-presidents, James A. Hart of Colorado Springs and R. C. Newton of Montclair, N. J.; secretary and treasurer, Guy Hinsdale of Philadelphia; Council, Isaac Hull Platt of Lakewood, N. J.; S. C. Solly of Colorado Springs; James B. Walker of Philadelphia; E. Fletcher Ingalls of Chicago, and E. O. Otis of Boston. Delegates to the Executive Committee of the Congress of American Physicians and Surgeons, F. I. Knight of Boston; alternate, Roland G. Curtin of Philadelphia.

The following were elected to active membership: Howard S. Anders of Philadelphia; Edward L. Baldwin of Saranac Lake; S. Westray Battle of Asheville; D. R. Brower of Chicago; L. D. Bulkley of New York; W. E. Casselberry of Chicago; Walter F. Chappell of New York; R. A. Cleemann of Philadelphia; E. C. Dudley of Chicago; Albert C. Getchell of Worcester, Mass.; Alexander Lambert of New York; Samuel K. Merrick of Baltimore; J. E. Stubbert of Liberty, N. Y.; James Tyson of Philadelphia; Herbert Whitney of Denver; Harold Williams of Boston; F. H. Williams of Boston. To corrresponding membership: G. G. Eyre of Claremont, Cape Town; Samuel Gache of Buenos Ayres; Eduardo Licéaga of Mexico; Domingo Orvañanos of Mexico; Carl Ruedi of Arosa, Switzerland; Septimus Sunderland of London; Clement L. Wragge of Brisbane, Australia.

The Association adjourned to meet in New York City in May, 1899.

THE USE OF THYROID.[1]

BY WILLIAM E. MOSELEY, M.D.,
OF BALTIMORE, MD.

AFTER hearing the very favorable report upon the use of thyroid in cases of bleeding fibroid, made by Dr. Polk in a paper read before the Baltimore Gynecological and Obstetrical Society last October, I determined to put all suitable patients who came under my care upon a like treatment and note the results. Believing that a study of the physiologic action of the drug would be of interest to this Society I requested Dr. E. L. Whitney, Lecturer on Clinical Pathology in the Baltimore Medical College, to make some investigations for me. This he kindly did, and I take great pleasure in presenting the report of his results as a part of this paper.

The cases which I have had under observation are only five in number and are as follows:

CASE I.—Mrs. C. S., aged forty-seven years, entered the Maryland General Hospital January 5, 1898. Her mother died of tuberculosis; otherwise her family history was negative, as was also the patient's early history. Menstruation began at twelve years, regular every four weeks, very free and accompanied by considerable pain until after the birth of her first and only child, which was born twenty-three years ago. Between 1880 and 1898 she suffered from a number of severe hemorrhages, which occurred independent of the menstrual period. During the past year menstruation has been irregular but excessive in amount.

Her uterus was found to be pretty regularly enlarged, the probe entering to a distance of seven inches. The endometrium bled freely on the touch of the probe. I curetted this uterus for the sake of having the endometrium examined microscopically, and put the patient on thyroid, 1 grain after each meal, to be increased 1 grain daily until 15 grains daily were taken. The pathologist's diagnosis from the scrapings was glandular hypertrophy with edema and congestion.

Since the operation the flow has been much reduced in amount and when the patient was last seen it was perfectly normal. The woman left the hospital on February 9th and was directed to continue the thyroid in doses of 9 grains daily. There have been no heart, kidney, or stomach symptoms.

CASE II.—H. M., female, aged thirty-three years, single, colored, entered the Maryland General Hospital January 5, 1898. One child born fifteen years ago, natural labor. No abortions. Family and early personal history negative. Menstruation began at seventeen, regular, lasting four or five days, no marked pain. During the preceding three months she had had a very free flow every two or three weeks and lasting eight or ten days, accompanied by severe pain. In November she had a profuse flow lasting two weeks, and was much debilitated on account of loss of blood.

Examination showed the uterus to be decidedly enlarged by intramural fibroids, but no measurements were taken. The patient was put upon thyroid, 3 grains daily, to be increased 1 grain each day until 15 grains daily were taken. She left the hospital February 16th and was directed to take 9 grains of thyroid daily and report every two weeks. There have been no heart, kidney, or stomach symptoms. The menstrual flow has been regular and normal, and the patient has improved much in general health.

CASE III.—E. C., female, single, white, aged fifty years, entered the Maryland General Hospital November 2, 1897. Family and early personal history negative. Menstrual flow free but fairly normal until five years ago, since which time the flow had been very excessive and accompanied by considerable pain in the pelvis and back. There had also been a free intermenstrual glairy leucorrhea. The patient's condition was one of extreme anemia, the mucous membranes appearing practically bloodless. The lungs were negative. There was a loud blowing systolic murmur, loudest over the base of the heart, and a loud bruit in both sides of the neck and also in the lower portion of the aorta. The uterus was symmetrically enlarged, forming a smooth, rather elastic tumor, 21 cm. between perpendiculars in its transverse and vertical diameters. The patient was ordered thyroid, 3 grains daily, to be increased 1 grain each day until 15 grains daily were taken. She was also ordered arsenic and reduced iron.

On December 14th the tumor measured 18 cm. in its transverse and 19 cm. in its vertical diameter. The patient had taken on flesh. There was a decided return of color to the mucous membranes and marked improvement in strength and in heart symptoms. The thyroid was continued in doses of 15 grains daily until February 11th, when the patient left the hospital, being directed to take 9 grains of the drug daily and to report from time to time. On May 18th I measured the tumor and found it 14 cm. in transverse, and 16 cm. in vertical diameter, a diminution of 7 and 5 cm. respectively. The bruit had entirely disappeared from the carotid arteries and there was but a slight soft murmur transmitted through the tumor from the aorta.

[1] Read at the Twenty-third Annual Meeting of the American Gynecological Society, held at Boston, May 24, 25, and 26, 1898.

The thyroid at no time caused any disturbance of the heart, kidneys, or stomach, and after beginning the use of the drug, the menstrual flow was excessive on only one occasion, and for the past few months has been very slight in amount.

Case IV.—Mrs. H. E. C., white, aged forty-six years, first entered my private hospital four years ago. Her family and early personal history were negative. Menstruation had been normal to within three years. Since 1891 the patient without any known cause had suffered from very severe menorrhagia, the flow lasting upward of two weeks out of every four. This condition had been ascribed to "change of life" and had been practically neglected by her family physician. On examination I made out nothing more than a moderate enlargement of the uterus and an endometrium that bled profusely on the introduction of a probe. I curetted the uterus thoroughly and put her upon tonics. For about three months there was relief from the menorrhagia, but later the flow became as free and as persistent as ever.
